Abstract—Forecasting time series data presents an emerging field of data science that has its application ranging from stock price and exchange rate prediction to the early prediction of epidemics. Numerous statistical and machine learning methods have been proposed in the last five decades with the demand for generating high-quality and reliable forecasts. However, in real-life prediction problems, situations exist in which a model based on one of the above paradigms is preferable, and therefore, hybrid solutions are needed to bridge the gap between classical forecasting methods and scalable neural network models. We introduce an interpretable probabilistic autoregressive neural network model for an explainable, scalable, and “white-box-like” framework that can handle a wide variety of irregular time series data (e.g., nonlinearity and nonstationarity). Sufficient conditions for asymptotic stationarity and geometric ergodicity are obtained by considering the asymptotic behavior of the associated Markov chain. During computational experiments, PARNN outperforms standard statistical, machine learning, and deep learning models on a diverse collection of real-world datasets coming from economics, finance, and epidemiology, to mention a few. Furthermore, the proposed PARNN model improves forecast accuracy significantly for 10 out of 12 datasets compared to state-of-the-art models for short to long-term forecasts.

Index Terms—Hybrid Forecasting, ARIMA, Autoregressive neural network, Ergodicity, Asymptotic stationarity.

I. INTRODUCTION

Time series forecasting has been a potential arena of research since last seven decades. Predicting the future has fundamental importance in various applied domain as it aids in better decision making and formulating data-driven strategies [1–3]. Recently, with the abundance of historical data there has been an increasing demand for forecasts in the industrial sectors as well [4, 5]. To serve the need of generating accurate and reliable forecasts numerous statistical and machine learning methods have been proposed in the literature [6]. One of the most popular statistical forecasting models, autoregressive integrated moving average (ARIMA) [7] model is a linear stochastic time series framework that tracks the linearity of a stationary data-generating process. Despite of its vast applicability, ARIMA is not suitable for modelling nonlinear datasets, as the model assumes the future values of the series to be a linear combination of the past.

Modern machine learning and deep learning tools such as multilayer perceptron (MLP) [8], auto-regressive neural network (ARNN) [9], ensemble deep learning [10], and recently developed PROPHET model [11] have proven to be useful for forecasting nonlinear datasets [12, 13]. However, these complex models often suffers from the problem of overfitting, i.e., it learns the pattern as well as the noise in the underlying data to such an extent that it negatively impacts the prediction capability in unseen data [14]. Another major drawback of some of the above-mentioned approaches are the explainability and “black-box-like” behavior of these models. In order to overcome the limitations arising from individual forecasting models and to simplify the model selection procedure, hybrid forecasting technique has been proposed in the literature [15–17]. The hybrid architecture comprises of three steps: firstly, the linear patterns of the series are forecasted which is followed by an error re-modelling step, and finally, the forecasts from both the steps are combined to produce the final output. These hybrid systems have been extended for forecasting applications in various domain such as finance [18], [19], earth science [20], [21], transportation [4], energy [22], [23], agriculture [24], epidemiology [25], [26] and their forecasting performance has surpassed their constituent models.

Although the hybrid forecasting models have outperformed all models in various applications, it is constructed based on certain assumptions. For instance, it is assumed that the linear and nonlinear patterns of a series can be modelled separately or that the residuals comprises of only the nonlinear trends or there exists an additive or multiplicative relationship between the linear and nonlinear segments of the datasets [26]. However, if these assumptions does not hold true i.e., if the existing linear and nonlinear components cannot be modelled separately or if the residuals of the linear model don’t contain valid nonlinear patterns or if there is a lack of linear relationship between the components of a series, then the performance of these hybrid models might degrade. However, majority of the real-world time series datasets may not satisfy any of these assumptions.

Motivated by these, we propose an assumption-free hybrid probabilistic autoregressive neural network model (PARNN) that is built to overcome the limitations of hybrid time series forecasting models while improving their predictive accuracies. The first phase of our proposal encompasses a linear ARIMA model fitting and generating in-sample residuals. During the second phase, these unexplained residuals are combined with the original input series and are remodeled using a nonlinear ARNN model. We built the proposed PARNN model in such a way that it becomes scalable, “white-box-like”, highly accurate, asymptotically stationary (which is of
particular interest from statistical point of view), and can handle a wide variety of irregularities of real-world complex time series. The proposed framework is experimented with twelve publicly available standard time series datasets. The experimental results infer that our proposed model can provide interpretable and robust predictions for nonlinear, non-stationary and non-Gaussian datasets and outperforms several statistical, machine learning, deep learning, hybrid, and ensemble forecasters for majority of the datasets.

The rest of the paper is organized as follows. In section II, we discuss the constituent methods of our proposed model. In Section III, we describe the formulation of the proposed probabilistic ARNN (PARNN) model and show its asymptotic behaviour. The experimental evaluation of our model on twelve publicly available time series datasets is provided in Section IV. Finally, we conclude the paper in Section V with some future scope of research.

II. BACKGROUND

Majority of the time series models are incapable of modelling the complexities of real world datasets. The performance of hybrid models in such situations is quite satisfactory. We try to improve the forecasting performance of hybrid models even further by proposing a hybrid PARNN model in this paper. Our proposed model comprises of the linear ARIMA model and nonlinear ARNN model. In this section we provide a brief description of the constituent models along with popularly used hybrid and ensemble models before describing our proposal.

A. Statistical Method: ARIMA Model

The classical autoregressive integrated moving average (ARIMA) model often termed as Box-Jenkins method [7] is one of the most widely used statistical models in forecasting literature. The ARIMA\((p, d, q)\) model comprises of three parameters where, \(p\) and \(q\) denotes the order of the AR and MA models and \(d\) denotes the order of differencing. The mathematical formula of ARIMA model is given by

\[
y_t = \beta_0 + \alpha_1 y_{t-1} + \alpha_2 y_{t-2} + \ldots + \alpha_p y_{t-p} + \varepsilon_t - \beta_1 \varepsilon_{t-1} - \beta_2 \varepsilon_{t-2} - \ldots - \beta_q \varepsilon_{t-q}
\]

where, \(y_t\) is the actual time series, \(\varepsilon_t\) is the random error at time \(t\), and \(\alpha_i\) and \(\beta_j\) are the model parameters. The ARIMA model is constructed using three iterative steps. Firstly, we convert a non-stationary series into a stationary one by applying the difference of order \(d\). Once, a stationary series is obtained we select the model parameters \(p\) and \(q\) from its ACF plot and PACF plot respectively. Finally, we obtain the “best fitted” model by analysing the residuals. For practical implementation, a built-in “auto.arima” function of the “forecast” package in R statistical software implements “best fitted” ARIMA model [27].

B. ML method: ARNN Model

Autoregressive neural network (ARNN) is a modification of the artificial neural network (ANN), specifically designed for modelling nonlinear time series dataset [9]. ARNN model comprises of a single hidden layer embedded within its input layer and output layer. The ARNN\((p, k)\) model passes \(p\) lagged values of input from its input layer to the hidden layer comprising of \(k\) hidden neurons. The value of \(k\) is determined using the formula \(k = \lfloor (p + 1)/2 \rfloor\) as proposed in [28]. After being trained by a gradient descent back-propagation approach [29], the final forecast is obtained as a linear combination of its predictors. The mathematical formulation of the ARNN model is given by:

\[
f(x) = \alpha_0 + \sum_{j=1}^{k} \alpha_j \phi (\beta_j + \theta_j x) ,
\]

where, \(f\) denotes a neural network, \(x\) is a \(p\)-lagged inputs, \(\alpha_0, \beta_j, \alpha_j\) are connecting weights, \(\theta_j\) is a weight vector of dimension \(p\) and \(\phi\) is a bounded nonlinear activation function. For practical implementation, the ‘nnetar’ function available in the “forecast” package in R statistical software implements ARNN model [27].

C. Ensemble and Hybrid models

In the context of forecasting literature, although ARIMA and ARNN models have individually achieved significant successes in their respective domains [30], [31], but their incompetency to model the complex autocorrelation structures within real-world datasets has led to the development of ensemble and hybrid forecasting approaches. The idea of ensemble forecasting model was first introduced in 1969 by [32]. The final output of these models was a weighted combination of the forecasts generated by its component models i.e.,

\[
\hat{y}(t) = \sum_{m=1}^{n} \alpha_m \hat{y}_m(t),
\]

where \(\alpha_i\) denotes the weights and \(\hat{y}_i(t)\) denotes the forecast generated from the \(i^{th}\) individual model. The ensemble models could significantly improve forecast accuracy for various applications, however, the appropriate selection of weights often termed as “forecast combination puzzle” posed a significant challenge in its universal success.

Recently, the concept of hybrid forecasting was introduced by Zhang in 2003 [15] where he assumed that a time series can be decomposed into its linear and nonlinear components as follows:

\[
y_t = y_{Lin_t} + y_{Nlin_t},
\]

where, \(y_{Lin_t}\) and \(y_{Nlin_t}\) denotes the linear and nonlinear elements respectively. Using a linear model (e.g., ARIMA) \(y_{Lin_t}\) was estimated from the available dataset. Let the forecast value of the linear model is denoted by \(\hat{y}_{Lin_t}\), then the model residuals, \(y_{Res_t}\), were computed as:

\[
y_{Res_t} = y_t - \hat{y}_{Lin_t}
\]

The left-out autocorrelations in the residuals were further re-modelled using a nonlinear model (e.g., ANN or ARNN) which generates the nonlinear forecasts as \(\hat{y}_{Nlin_t}\). The final
forecast \( \hat{y}_t \) is computed by adding the out-of-sample forecasts generated by the linear and the nonlinear models i.e.,

\[
\hat{y}_t = \hat{y}_{Lin_t} + \hat{y}_{Nlin_t}.
\]

Various combination of hybrid models have been proposed in the literature that have shown to reinforce the forecasting performance [16], [33–35] out of which ARIMA-ARNN model promised higher accuracies for epidemic [17] and econometric modeling [19]. Practical implementation of several ensemble models can be done using an R package called “forecastHybrid” [36] and for hybrid models, one refers to the following publicly available Github repository.

III. PROPOSED MODEL

A. Proposed PARNN model

We propose a semi-parametric hybrid probabilistic autoregressive neural network (PARNN) model which is a generalization of the artificial neural network (ANN\((p, d, q)\)) [37] and recurrent neural network (RNN) model [38] for nonlinear time series forecasting. The current progress of hybrid models in time series [15], namely hybrid ARIMA-ARNN model [17], made a significant improvement on the predictive accuracies of past observations and the residual \( \varepsilon \), namely hybrid ARIMA-ARNN model [17], with least RMSE score is selected i.e.,

\[
(p, q) = \arg \min_{p, q} \frac{1}{n} \sum_{i=1}^{n} (y_i - \hat{y}_i)^2.
\]

Proposed PARNN is a hybrid framework in which ARIMA is embedded into an ARNN model which converges very fast. This probabilistic approach is shown to be asymptotically stationary and outperforms several state-of-the-art classical, machine learning, deep learning, hybrid and ensemble models considered in this study.

B. Asymptotic Stationarity and Ergodicity of the PARNN model.

This section deals with asymptotic stationarity and ergodicity of the proposed PARNN model from nonlinear time series perspective. We develop their theoretical structure and describe their practical implications and applications. For simplicity, we consider simple PARNN(1,1) process which is defined by the stochastic differential equation of the following form:

\[
y_t = f(y_{t-1}, e_{t-1}, \Theta) + \varepsilon_t,
\]

where \( f(y_{t-1}, e_{t-1}, \Theta) \) denotes an autoregressive neural network with input \( y_{t-1} \), ARIMA feedback \( e_{t-1} \), weight vector \( \Theta \) and \( \varepsilon_t \) denotes a sequence of independent and identically distributed (i.i.d) random shocks. The output of the PARNN(1,1) with an activation function \( G \) and \( k \) hidden units in the hidden

\[
y_t = f(y_{t-1}, e_{t-1}, \Theta) + \varepsilon_t,
\]

The proposed PARNN model consists of two stages. In the first stage, the residual series \( (e_t) \) is generated using an autoregressive integrated moving average (ARIMA) model. In the second stage, an autoregressive neural network is used in order to model the nonlinear and linear relationships existing in ARIMA residuals and original observations. A formal workflow of our proposal is given in Algorithm [11].

Proposed PARNN is useful for the modeling the underlying data generating process with nonlinear, non-stationary and non-Gaussian structures in the time series data. Nonlinear ARMA and simple ARNN model arises as a special cases of the proposal. It can be seen that in the PARNN\((p, k, q)\) model, in contrast to the traditional hybrid models no prior assumption is considered for the relationship between the linear and nonlinear components and it will be generally estimated by the neural network. Additionally, it can be generally guaranteed that the performance of the probabilistic ARNN model will not be worse than either of the components – ARIMA and ARNN – used separately or used in a hybridized manner. The number of hidden nodes in the hidden layer is set to \( k = \left\lceil (p+q+1)/2 \right\rceil \) based on the recommendation of [38]. The choice of \( p \) and \( q \) is based on a grid search. We determine the optimal values of the hyperparameters \( p \) and \( q \) by performing a grid search algorithm. The maximum values of both the hyperparameters are usually set to 10, and the model is iterated over a grid of \( p \) and \( q \) values. At each iteration, the model is fitted for different pairs of values of \( p \) and \( q \) and the forecasts \( \hat{y}_t \) are generated. The performance of these fitted models are evaluated for all possible pairs of \( p \) and \( q \) and eventually, the pair of values with least RMSE score is selected i.e.,

\[
(p, q) = \arg \min_{p, q} \frac{1}{n} \sum_{i=1}^{n} (y_i - \hat{y}_i)^2.
\]

The proposed PARNN model consists of two stages. In the first stage, the residual series \( (e_t) \) is generated using an autoregressive integrated moving average (ARIMA) model. In the second stage, an autoregressive neural network is used in order to model the nonlinear and linear relationships

\[
y_t = f(y_{t-1}, e_{t-1}, \Theta) + \varepsilon_t,
\]

The proposed PARNN model consists of two stages. In the first stage, the residual series \( (e_t) \) is generated using an autoregressive integrated moving average (ARIMA) model. In the second stage, an autoregressive neural network is used in order to model the nonlinear and linear relationships

\[
y_t = f(y_{t-1}, e_{t-1}, \Theta) + \varepsilon_t,
\]

The proposed PARNN model consists of two stages. In the first stage, the residual series \( (e_t) \) is generated using an autoregressive integrated moving average (ARIMA) model. In the second stage, an autoregressive neural network is used in order to model the nonlinear and linear relationships

\[
y_t = f(y_{t-1}, e_{t-1}, \Theta) + \varepsilon_t,
\]

The proposed PARNN model consists of two stages. In the first stage, the residual series \( (e_t) \) is generated using an autoregressive integrated moving average (ARIMA) model. In the second stage, an autoregressive neural network is used in order to model the nonlinear and linear relationships
Now, we show the ergodicity and stationarity of the overall PARNN process. A single realization \( \psi \) is a particular case of PARNN process with no feedback connections, i.e., \( \psi \) is a linear function of its arguments. Also, nonlinear ARNN(1) process is a generalization of ARMA(1,1) process, where \( f \) is a linear function of the ARIMA residuals.

Our proposed PARNN model can be thought as a generalization of ARIMA(1,1) process, where \( f(\cdot) \) is a linear function of its arguments. Also, nonlinear ARNN(1) process is a particular case of PARNN process with no feedback connections, i.e., \( \psi_2 = \phi_{1,2} = 0 \).

Now, we show the ergodicity and stationarity of PARNN(1,k,1) process. The ergodicity and stationarity of a process is of special significance from statistical point of view in the domain of nonlinear time series analysis. In particular, we find that the fundamental property of irreducibility of the associated Markov chain which further determines upon some regularity conditions the ergodicity and stationarity of the overall PARNN process.

To start with, we define the irreducibility of a Markov chain which fundamentally considers the structure of a Markov chain in which all parts of the state space can be reached by the Markov chain irrespective of the starting point. A more formal definition of irreducibility is stated below.

**Definition 1.** A Markov chain is called irreducible if \( \sum_{t=1}^{\infty} P^t(x,A) > 0 \) for all \( x \in X \), whenever \( \lambda(A) > 0 \), where \( P^t(x,A) \) denotes the transition probability from the state \( x \) to the set \( A \in B \) in \( t \) steps, state space \( X \subseteq \mathbb{R}^2 \), \( B \) is the usual Borel \( \sigma \)-field and \( \lambda \) be the Lebesgue measure.

Another foremost property of Markov chains is aperiodicity. A Markov chain is said to be aperiodic if there are no (infinitely often repeated) cycles. Hence, we show the conditions under which PARNN process is irreducible and aperiodic using \[49\].

Now, we write PARNN in the state space form

\[
x_t = \Psi x_{t-1} + F(x_{t-1}) + \sum \varepsilon_t,
\]

where \( x_t = (y_t, \varepsilon_t)' \), \( \sum = (1,1)' \), \( \Psi = \begin{bmatrix} \psi_1 & \psi_2 \\ 0 & 0 \end{bmatrix} \) and \( F(x_{t-1}) = (g(y_{t-1}, \varepsilon_{t-1}, \beta, \phi), 0)' \) is the nonlinear part.

Then, we say \( x_t \) be a Markov chain with state space \( X \subseteq \mathbb{R}^2 \) equipped with Borel \( \sigma \)-field \( B \) and Lebesgue measure \( \lambda \). In contrast to pure AR processes, irreducibility does not hold almost surely for the PARNN state space model. For example, consider the following PARNN process:

**Example 1.** Consider Eqn.\[3\] and assume that the linear part vanishes. Now, the nonlinear part of an autoregressive neural network is bounded, i.e., \( ||F(\cdot)|| < M < \infty \), where \( || \cdot || \) denotes the Euclidean norm, then the set \( C = \{(x,y) \in \mathbb{R}^2; |x-y| \geq M\} \) can never be reached by the Markov chain.

Though the above example is a trivial one but it is an example of reducible Markov chain. To establish the results for irreducibility of the state space model, we write Eqn.\[3\] as a control system driven by the control sequence \( \{\varepsilon_t\} \): \( x_t = F_t(x_0, \varepsilon_1, \ldots, \varepsilon_t) \), where the definition of \( F_t(\cdot) \) follows the inductively from Eqn.\[3\]. There is a close relation between the irreducibility and the concept of forward accessibility from control theory perspective, for details see [39]. The concept of forward accessibility roughly means that the set of reachable states is not concentrated in some lower dimensional subset of \( X \). Forward accessibility together with an additional assumption on the noise process is essential to ensure the irreducibility of the corresponding Markov process. A formal definition of forward accessible control system is as follows.

**Definition 2.** Let \( A^i_t(x) \) be the set of all states which are accessible from \( x \) at time \( t \), we set \( A^0_t := \{x\} \) and \( A^i_t(x) := \{F_t(x_0, \varepsilon_1, \ldots, \varepsilon_t); \varepsilon_i \in \Theta\} \), where the control set \( \Theta \) is an open set on the real line \( \mathbb{R} \). Then the control system \( F_t(\cdot) \) is said to be forward accessible if the set \( \bigcup_{t=0}^{\infty} A^i_t(x) \) has nonempty interior for each \( x \in X \).
Now, we rewrite the control system in Eqn. \(3\) as follows:

\[
x_t = \Psi x_{t-1} + F(x_{t-1}) + \sum_x \varepsilon_t \\
= \Psi^2 x_{t-2} + \Psi F(x_{t-2}) + F(x_{t-1}) \\
+ (\psi_1 + \psi_2, 0)\varepsilon_{t-1} + (1, 1)\varepsilon_t,
\]

(4)

Consider the following special case of a linear system \((F \equiv 0)\): every point of the state space can be reached irrespective of the starting point for some control values \(\varepsilon_{t-1}\) and random variable \(\varepsilon_t\). The linear control system \(F_t\) is then called controllable. Below we present the assumptions under which the control model \(3\) is forward accessible.

**Proposition 1.** The control system in Eqn. \(3\) is forward accessible if the following assumptions hold:

(a) \(G \in C^\infty\) is a bounded, nonconstant and asymptotically constant function.

(b) The linear part in Eqn. \(3\) is controllable, i.e., \(\psi_1 + \psi_2 \neq 0\).

**Proof.** Most popularly used activation functions (e.g., logistic and tanh squasher) satisfy assumption (a). Assumption (b) implies the non-vanishing (controllability) of the linear part of Eqn. \(3\).

Since assumption (a) holds for the proposed PARNN model, then for any choice of \(k \in \mathbb{Z}^+\) (number of hidden units of the neural network is always a positive integer) and any scalars \(\beta, \beta_i, \mu_i\) and \(\phi_i \neq 0\) \((i = 1, 2, \ldots, k)\), the condition

\[
\beta_0 + \sum_{i=1}^k \beta_i G_i(\phi_i x + \mu_i) = 0, \ \forall \ x \in \mathcal{R}
\]

implies \(\beta_0 = 0\) (from assumption (a)). Also, we define the generalized controllability matrix as follows: \(C_{\beta_0} = \begin{bmatrix} c & 1 \\ 0 & 1 \end{bmatrix}\), where \(c = \psi_1 + \psi_2 + \sum_{i=1}^k \beta_i(\phi_{i,1} + \phi_{i,2})G_i((\phi_{i,1} + \phi_{i,2})\varepsilon_1 + \phi_{i,1}\psi_1 + \mu_i)\).

It is straightforward to show that for all \(\psi_1\), there exists \(\varepsilon_1 \in \theta\) such that \(c \neq 0\). We set \(\theta \equiv \mathcal{R}\) and choose \(\psi_1\) aptly. Thus, assumption (b) in Prop. \(4\) implies that \(c \neq 0\) for at least one \(\varepsilon_1 \in \theta\). This indicates that \(C_{\beta_0}\) is non-singular and therefore the control system in Eqn. \(3\) is forward accessible. \(\square\)

In the theorem stated below, we show the irreducibility of the corresponding Markov chain for the PARNN process under a regularity condition on the distribution of the noise process \(\varepsilon_t\).

**Theorem 1.** (Irreducibility) Suppose the distribution of the noise process \(\varepsilon_t\) is absolutely continuous with respect to the Lebesgue measure \(\lambda\). Also, assume that the probability distribution function \(\nu(\cdot)\) of \(\varepsilon_t\) is positive everywhere in \(\mathcal{R}\) and lower semi-continuous everywhere. Then, the Markov chain in Eqn. \(3\) is irreducible on the state space \((\mathcal{R}^2, \mathcal{B})\) if the conditions in Prop. \(4\) is satisfied.

**Proof.** It is straightforward to see that \(x^* = (0, 0)\) is a globally attracting state from the control system in Eqn. \(3\) The second component of \(x_t\) can trivially reach the point \(0\) in one-step irrespective of the starting point. From time point \(t = 0\) to the time point \(t = 2\), the iterated first component can be written as \(x_2 = \ldots + (\psi_1 + \psi_2)\varepsilon_2 + g(\ldots + \varepsilon_1, \varepsilon_1, \beta, \phi)\). Since \(\psi_1 + \psi_2 \neq 0\) and activation function \(g(\cdot)\) is bounded and continuous everywhere, then the first component can reach \(0\) in two steps irrespective of the second component and the starting point. Using the same argument, we say that every state in \(\mathcal{R}^2\) can be reached in two steps and the state space is connected. This concludes that the Markov chain in Eqn. \(3\) is irreducible and aperiodic. \(\square\)

**Remark 2.** (a) A trivial example is Gaussian white noise that fulfills the conditions of Theorem \(4\). Theorem \(4\) discusses the fundamental property of irreducibility for the simple PARNN process and its close relationship to the concept of forward accessibility of the control system. In contrast to the pure AR process, we show that the simple PARNN process exists that are not forward accessible but exhibit asymptotic stationarity. In those cases, it is often impossible to recover the data generating process from the observed data.

(b) Prop. \(7\) shows the controllability of the linear part of the PARNN control system implying forward accessibility. Although the condition is only sufficient but not necessary. But, if the support of the distribution of the noise process is sufficiently large, then the associated Markov chain is irreducible.

Once the irreducibility is established, we show the (strict) stationarity of the state-space form defined in Eqn. \(3\). The stationarity of a Markov chain \(x_t\) is closely related to the geometric ergodicity of the associated process. An implication of a geometric ergodic process is that the underlying distribution of the process converge to the unique stationary solution at a geometric rate for its initials. A formal definition of geometric ergodicity and asymptotic stationarity is stated below [39].

**Definition 3.** A Markov chain \(\{x_t\}\) is called geometrically ergodic if there exists a probability measure \(\Pi\) on a probability triple \(\langle \mathcal{X}, \mathcal{B}, \lambda \rangle\) and a constant \(\rho > 1\) such that

\[
\lim_{t \to \infty} \rho^t ||P^t(x, \cdot) - \Pi(\cdot)|| = 0 \text{ for each } x \in \mathcal{X}
\]

\(\Pi(\cdot)\) denotes the total variation norm. Then, we say the distribution of \(\{x_t\}\) converges to \(\Pi\) and \(\{x_t\}\) is asymptotically stationary.

Recall that the asymptotic stationarity results for the hybrid ARIMA-ARNN model in [19] showed that the nonlinear part and the feedback term have no influence on the stability of time series points \(y_t\). Here, we extend the idea to show the geometric ergodicity of the PARNN(1, k, 1) process in the next theorem.

**Theorem 2.** (Ergodicity) Let the Markov chain \(\{x_t\}\) of the PARNN(1, k, 1) process satisfies the conditions of Theorem \(4\) and \(E[|\varepsilon_t|] < \infty\). A sufficient condition for the geometric ergodicity of the Markov chain \(\{x_t\}\) is that \(|\psi_1| < 1\).
Proof. Recall the state-space model in Eqn. [3] and we define
the following matrix:
\[
\Psi := \begin{bmatrix}
\psi_1 & \psi_2 & \cdots & \psi_{p-1} & \psi_p \\
1 & 0 & \cdots & 0 & 0 \\
0 & 1 & \cdots & 0 & 0 \\
\vdots & \vdots & \ddots & \vdots & \vdots \\
0 & 0 & \cdots & 1 & 0
\end{bmatrix}
\]
and \(x_t = \Psi x_{t-1} + F(x_{t-1}) + \epsilon_t\), where \(F(\cdot)\) is the nonlinear part and the intercept. There exists a transformation \(Q\) such that \(\Gamma = Q \Psi Q^{-1}\) has the eigenvalues of \(\Psi\) along its diagonal and arbitrarily small off-diagonal elements. Further, we define a test function \(V(x) = ||\sum x||\) and the test set \(\tau = \{x \in \mathbb{R}^p, V(x) \leq c\}\) for some \(c < \infty\). Then, we have
\[
E[V(x_t)|x_{t-1} = x] \leq ||Q\Psi x|| + ||QF(x)|| + E||Q\epsilon|| \\
\leq (||\Lambda|| + ||\Delta||) V(x) + ||QF(x)|| + E||Q\epsilon||,
\]
where \(\Lambda = diag(\Gamma)\) and \(\Delta = \Gamma - \Lambda\). By the assumption of the theorem, we have \(||\Lambda|| < 1\) and \(Q\) can be chosen in such a way that \((||\Lambda|| + ||\Delta||) < 1 - \epsilon\) for some \(\epsilon > 0\). Since the second and third term are bounded, we can choose \(\epsilon\) such that \(E[V(x_t)|x_{t-1} = x] \leq (1 - \epsilon) V(x) + \delta \lambda(x)\) for some \(0 < \delta < \infty\) and for all \(x\). The result is also valid for the test function \(V(x) + 1\) and hence, we get the desired result. \(\square\)

Remark 3. Theorem 2 states the sufficient condition for the geometric ergodicity of the PARNN(1, k, 1) process. Consider the following particular case: Suppose \(\psi_1 = 1\), then the long-term behaviour of the PARNN process is determined using the nonlinear part of the control system together with the intercept term of the process.

C. Interpretations and Practical Implications.

Some interpretation and practical implication of the theoretical results presented above are given below:

• The geometric rate of convergence in Theorem 2 implies that the memory of PARNN(1, k, 1) process vanishes exponentially fast. The major finding of the theoretical results presented above is that the weight corresponding to the autoregressive part of the proposal determines whether the overall PARNN(1, k, 1) process is ergodic and asymptotically stationary.

• From practitioners’ viewpoint, if an irreducible PARNN model is estimated from an observed time series data, the estimated weights are not too far from the true weights. But, if the conditions are not met, the model is likely to be unspecified and the estimation procedure of the weights of the model should be done cautiously.

• Theoretical results for the PARNN(1, k, 1) process are presented in this study. However, under similar conditions, the results can be extended for the general PARNN(p, k, q) class.

IV. EXPERIMENTAL ANALYSIS

In this section, we analyse the performance of our proposed PARNN model by simulating the experimental results on twelve open-access time series datasets and compare its efficiency with other state-of-the-art forecasting models from statistical and machine learning literature.

A. Data

The datasets used for the analysis exhibits distinct patterns and are collected from a wide range of applied domains. The frequency and the forecasting horizon of these datasets are also different to show the scalability of the proposal. A brief description about the standard datasets are given below.

1) Daily datasets: We have considered five daily datasets in our study, this includes data from macro-economic and demographic background.

(a) Births dataset: This benchmark dataset comprises of the number of births reported daily in the U.S. during 1968-1988. This benchmark dataset is available in the “mosaicData” R package as “Births”.

(b) Stock market data: We have gathered daily close prices of Microsoft Corporation (MSFT), Tesla Inc (TSLA) and Netflix Inc (NFLX) from Yahoo Finance for the time period 2011 to 2021.

(c) Bitcoin price: This dataset is extracted from [kaggle repository](https://www.kaggle.com/) It comprises of daily close price of Bitcoin from 29/04/2013 to 06/07/2021 (DD/MM/YYYY format).

2) Weekly datasets: Epidemiological datasets and exchange rate dataset comprising of weekly values have been used for the experimentation.

(a) Epidemiological Data: We have used three epidemic datasets from open-sourced Github repository in our study. It comprises of weekly malaria and dengue incidence data of Columbia and malaria incidence data of Venezuela. The time span for Columbia dataset ranges from 2005-2016 and for Venezuela it is from 2002-2014.

(b) National Exchange Rate for China: This dataset is collected from FRED database for the time-span 2000-2021. It comprises of daily exchange rates in currency units per U.S. dollars. However, for our analysis we have considered weekly average of the exchange rate.

3) Monthly datasets: The monthly datasets used for the experimentation purpose arise from macro-economic domain and provides us valuable information regarding the economic and social conditions of a country. We have collected Economic Policy Uncertainty Index for United States (US-EPU Index) dataset, Unemployment Rate in the United Kingdom (UK-unemployment) dataset and Exchange Rate data of Russia (Russia Exchange) from FRED database. For US-EPU Index dataset and Russia Exchange dataset we have considered a subset of data ranging from 2000-2021 and for UK unemployment dataset the selected time span is 1971-2021.
B. Analysing Global Characteristics in the datasets

We have examined the characteristics of these twelve datasets using KPSS test (nonstationarity test), Teräsvirta test (non-linearity test), and Anderson-Darling test (normality test) [28]. Table 1 gives the p-value obtained for each datasets on performing these tests. Using the function ‘terasvirta.test’ from the R package “tseries”, we have performed the test. We have tested the null hypothesis that the time series is stationary around a deterministic trend using the ‘kpss.test’ function available in the “tseries” package of R statistical software. We have utilized the ‘ad.test’ function from the R package “nortest” package. The p-values for all the datasets provides evidence to reject the null hypothesis that the data generating process follows a Gaussian distribution.

C. Performance Measures

The forecasting performance of our proposed model is evaluated using the Root Mean Square Error (RMSE), Mean Absolute Scaled Error (MASE), and Symmetric Mean Absolute Percent Error (SMAPE) [28, 43]. The mathematical formulae of these metrics are given below:

\[
RMSE = \sqrt{\frac{1}{n} \sum_{i=1}^{n} (y_i - \hat{y}_i)^2};
\]

\[
MASE = \frac{\sum_{i=M+1}^{M+n} |y_i - \hat{y}_i|}{\sum_{i=S+1}^{M+n} |y_i - y_{i-s}|};
\]

\[
SMAPE = \frac{1}{n} \sum_{i=1}^{n} \frac{|y_i - \hat{y}_i|}{(|y_i| + |\hat{y}_i|)}/2;
\]

where \(y_i\) is the actual value, \(\hat{y}_i\) is the predicted output, \(n\) is the forecast horizon, \(M\) denotes the size of training data, and \(S\) is the seasonality of the dataset. By convention, the model with least accuracy measure is considered to be the ‘best’ model.

D. Results

For the experimentation, we have trained all the datasets with classical models - ARIMA [7], Self-exciting autoregressive (SETAR) [44]; smoothing models - Error Trend and Seasonality (ETS) [45], TBATS: Trigonometric B: Box-Cox transformation. A: ARIMA errors. T: Trend. S: Seasonal Components) [46], Theta [47]; advanced models - Wavelet ARIMA (WARIMA) [48], PROPHET [11]; machine learning model - ARNN [9]; hybrid ARIMA-ARNN model [17]; ensemble ARIMA-Theta-ARNN model [49] model (denoted by ensemble model in the Table III) along with our proposed PARNN model and compared the out-of-sample predictions for each model.

The model training has been done in following manner: We have initiated the training procedure by fitting an ARIMA model using the ‘auto.arima’ [27] function of R statistical software. The best fitted model, selected using the Akaike information criterion (AIC), is employed to estimate the in-sample as well as out-of-sample predictions for a desired forecasting horizon. After the predictions are generated we compute the residual values and apply an error correction approach to model the original time series along with the left out ARIMA residuals using our proposed PARNN(p, k, q) model. We provide a combined input comprising of \(p\)-lagged values of the original time series and \(q\)-lagged values of the ARIMA residuals to the PARNN(p, k, q) model. In order to ensure that the forecast values remain positive we apply a Box-Cox transformation with \(\lambda = 0\). The weights of the neural network is trained using a gradient descent back-propagation approach [29]. The optimal values of the hyperparameters \(p\) and \(q\) are selected using a grid-search algorithm, and the number of hidden neurons in the hidden layer is set to \(k = \lceil(p + q + 1)/2\rceil\) [28]. We iterate the training over 500 repetitions and obtain the final forecast of our PARNN model as the average output of these networks. In case of, Columbia Malaria dataset ARIMA(1,1,2) model was fitted and \(AIC = 8168.85\) was obtained. Further, the model residuals and the training data were remodelled using PARNN(2,2,2) model. The final forecast was obtained as the average output of 500 networks, each of which is a 6-4-1 network with 33 weights. The predicted values are then used to evaluate the model performance and are reported in Table III. In a similar manner, we fit a PARNN model to the other datasets by using the training data and the residuals generated from ARIMA model. The proposed model specification that were used for different datasets are tabulated in Table III.

We have implemented the other individual models like ETS, TBATS, Theta, and ARNN models using the “forecast” [50] package in R statistical software. SETAR model was fitted using the ‘setar’ function of “tsDyn” [51] package in R, for the WARIMA and PROPHET model we have used the “WaveletArima” [52] and “prophet” [11] functions in R and Python respectively. For the ensemble model we have utilized the “forecastHybrid” [36] package of R. The hybrid ARIMA-ARNN model was fitted using the implementation provided in [github repository]. All the above mentioned models were applied to the twelve datasets and the experimental results are reported in Table III. On analysing the accuracy measures of different models across all the datasets we can infer that in terms of SMAPE and MASE scores, our proposed model outperformed all other individual, hybrid and ensemble forecasting models except for TSLA stock price dataset and Columbia Dengue dataset. The time series plot of TSLA stock price dataset exhibits a conceptual shift this results in the failure of linear models. However, SETAR model provides the best forecast for this dataset and our proposed PARNN model provides the second best. Similarly, for Columbia Dengue dataset we can notice that Prophet model outperforms all other models that have been used for comparison. In case of RMSE scores, our PARNN model yields outperforming forecast for all datasets but for MSFT stock price, TSLA stock price, and Columbia Dengue datasets it yields competitive results. A graphical representation of training and testing datasets along with predicted test results of proposed PARNN model is presented in Fig. I for visual comparison.

V. CONCLUSION AND DISCUSSION
In this paper, we have presented a novel hybrid forecasting model using an interpretable probabilistic approach. The proposed PARNN model is created by embedding the classical autoregressive integrated moving average model into an autoregressive neural network framework. This makes the proposal capable of handling various data irregularities (nonlinearity, nonstationarity and non-Gaussian time series) in a white-box framework for which it is not required to choose the hidden units in the neural net by trial and error method. The proposed PARNN model produces highly competitive forecasts for short, medium, and long-range forecast horizons validated on standard time series datasets from a wide range of applied domains. Our experimental results reveal that the hybrid model captures time series datasets’ linear and nonlinear patterns and produces a better forecast than competing models, namely ARIMA and ARNN. The significant advantage of the proposed ARIMA and ARNN model is that it may work as a combinationist between statistical time series models with that of a scalable neural network model. Due to this, the proposal is explainable, scalable, and highly competitive as compared to commonly...
used single, hybrid and ensemble forecasters. Finally, we can conclude that our proposed model adds a new segment to the hybrid forecasting framework by not considering any implicit assumptions regarding the linear and nonlinear components of the dataset and can be useful to forecasting practitioners for handling real-world challenges. Theoretical robustness of the PARNN model is shown by providing asymptotic properties of the proposed model, which adds value to the nonlinear time series literature. An immediate extension of this work would be to extend this model for forecasting multivariate time series and to show the asymptotic behavior of the most general PARNN\((p, k, q)\) model.
