Abstract—Pruning is an effective way to reduce the huge inference cost of large Transformer models. However, prior work on model pruning requires retraining the model. This can add high cost and complexity to model deployment, making it difficult to use in many practical situations. To address this, we propose a fast post-training pruning framework for Transformers that does not require any retraining. Given a resource constraint and a sample dataset, our framework automatically prunes the Transformer model using structured sparsity methods. To retain high accuracy without retraining, we introduce three novel techniques: (i) a lightweight mask search algorithm that finds which heads and filters to prune based on the Fisher information; (ii) mask rearrangement that complements the search algorithm; and (iii) mask tuning that reconstructs the output activations for each layer. We apply our method to BERT\textsubscript{BASE} and DistilBERT, and we evaluate its effectiveness on GLUE and SQuAD benchmarks. Our framework achieves up to $2.0 \times$ reduction in FLOPs and $1.56 \times$ speedup in inference latency, while maintaining $<1\%$ loss in accuracy. Importantly, our framework prunes Transformers in less than 3 minutes on a single GPU, which is over two orders of magnitude faster than existing pruning approaches that retrain. Our code is publicly available.

I. INTRODUCTION

In recent years, the Transformer [74] has become a de facto standard model architecture in Natural Language Processing [4, 11, 43], and it is becoming common in Computer Vision [13, 45, 73] and Speech Recognition [2, 7, 24] as well. However, efficient deployment of Transformer architectures has been challenging due to their large model size and high latency. To address this, structured pruning has become a promising technique for efficient Transformer deployment.

While prior work on pruning Transformers substantially reduces inference time, it is often difficult to use in practice for several reasons. First, previous approaches require retraining the pruned model and/or jointly learning the pruning configurations during training. For instance, Block Movement Pruning [36] increases the training time by $10 \times$ for pruning. Such additional training adds significant computational overhead, given the large training cost of Transformers. Second, previous methods add many moving parts to the model deployment process. Pruning pipelines are often complex and involve additional hyperparameter tuning. For instance, ROSITA [44] uses a three-stage knowledge distillation [22] with sophisticated pruning schedules. Such techniques demand significant engineering efforts for reproducing and debugging, which impedes their adoption in production pipelines. Third, these previous methods do not directly adapt to the users’ FLOPs/latency constraints. They either rely on vague regularization hyperparameters or fixed architectures selected independently of the user settings. This can

\*Equal contribution.
result in sub-optimal models not tailored for the given constraint and target hardware.

To address these limitations, we propose a fast post-training pruning framework for Transformers that does not require any retraining of the models. As illustrated in Figure 1, our framework takes as input a Transformer model, a sample dataset, and a FLOPs/latency constraint. It then outputs a pruned Transformer model that can be deployed immediately. By avoiding expensive retraining, the end-to-end compression pipeline can be extremely fast and simplified, typically in a few minutes, without any user interventions that complicate the whole process.

Indeed, post-training compression has been widely studied for quantization, and it gained considerable attention in both academia and industry [3, 26, 91]. Although quantization-aware training methods achieve higher compression rates in general, post-training quantization (PTQ) has often been more preferred in practice due to its retraining-free advantage. PTQ allows quantization to happen seamlessly when deploying models through the various frameworks such as TensorRT [53], TFLite [17], and OpenVINO [28]. Similar to these PTQ frameworks, our framework provides an out-of-the-box tool that enables pruning of Transformers without engineering efforts.

Our contributions can be summarized as follows:

- We propose a novel post-training pruning framework for Transformers that does not require model retraining. To retain accuracy without retraining, our framework consists of three stages of: (i) the mask search process guided by the Fisher information matrix to find which heads/filters to prune (Section IV-A); (ii) the mask rearrangement process that rearranges the pruned heads/filters by capturing intra-layer interactions (Section IV-B); and (iii) the mask tuning process that adjusts the mask variables to ensure that the output signal is recovered for each layer (Section IV-C).
- We extensively test our framework by applying it to BERT base and DistilBERT on GLUE and SQuAD tasks (Section V-B). With 1% of accuracy drop, our framework reduces 30–50% of the original FLOPs (Figure 4), resulting in up to $1.56 \times$ speedup on an NVIDIA V100 GPU (Table I).
- We show that our method achieves comparable or even better FLOPs-accuracy trade-off than prior structured pruning methods without retraining (Section V-C, Figure 5). Our end-to-end pruning finishes in only 39 and 135 seconds on average for GLUE and SQuAD (Section V-D, Table IV), which is over $100 \times$ faster than the retraining methods.
- We open-source our framework at GitHub\(^1\), along with the model checkpoints used in our experiments.

II. RELATED WORKS

Efficient Transformers. In order to improve inference speed and reduce memory footprint of Transformers, multiple different approaches have been proposed. These can be broadly categorized as follows: (i) efficient architecture design [27, 34, 37, 69, 79, 85]; (ii) hardware-software co-design [18, 19, 70, 78]; (iii) knowledge distillation [30, 60, 68, 80]; (iv) quantization [32, 63, 89, 90]; (v) neural architecture search [6, 64, 65, 77, 86, 88]; and (vi) pruning. Here, we focus only on pruning and briefly discuss the related works.

Transformers Pruning. Pruning has been a popular choice for reducing unimportant weights and redundant parts in Transformers. Pruning can be broadly categorized into unstructured and structured pruning. For unstructured pruning, magnitude-based pruning [16], the lottery-ticket hypothesis [8, 9, 15, 55], movement pruning [61] have been explored for Transformers. While these methods compress the model size, commodity hardware cannot take advantage of the unstructured sparsity for speedup.

For this reason, a number of structured pruning methods have been introduced to remove structured sets of parameters. For example, [48, 75] drop attention heads in multi-head attention layers. Another thread of work prunes entire Transformer blocks based on a simple heuristic [59] or an adaptive training using a layer-wise dropout method [14]. Relatedly, [81] structurally prunes weight matrices via low-rank factorization and $l_0$ regularization: [31, 41] attempt to jointly prune attention heads and filters of weight matrices; and [23, 46] take a step further by dynamically determining the pruning configurations at run time. Recent block pruning schemes chunk weight matrices into blocks and prune them based on group Lasso optimization [40], adaptive regularization [87], and movement pruning [36].

While the structured pruning techniques have achieved high compression rates and speedups, the improvement largely attributes to retraining of the models during or after pruning, often combined with knowledge distillation. However, model retraining introduces several practical problems. Most notably, retraining in general increases training time significantly. For instance, Block Movement Pruning [36], a state-of-the-art structured Transformer pruning method, requires $10 \times$ longer training time than normal fine-tuning. In addition, the extra hyperparameters

\(^1\)https://github.com/WoosukKwon/retraining-free-pruning
introduced by the pruning methods add additional moving parts and lead to increased training cost.

**Post-training Model Compression.** Post-training compression methods have been widely studied in quantization. These methods, categorized as post-training quantization (PTQ), perform quantization without any retraining, thereby minimizing the training cost and user intervention. Multiple approaches have been proposed for PTQ in order to mitigate the accuracy degradation without retraining, including analytic computation of optimal clipping ranges [3], outlier channel splitting [91], and adaptive rounding methods [26, 51].

Although not as much as for quantization, post-training schemes have also been explored for unstructured [25, 71] and structured pruning. For structured pruning, [67] proposes to detect and merge similar convolution filters iteratively, and [33] compensates for the information loss due to pruning by merging similar neurons based on cosine distance. While these methods are effective for CNNs, their applicability is limited to models with simple architectures, and they rely on the characteristics of ReLU nonlinearity [25, 33]. Hence, the prior methods cannot be extended to the general Transformer architectures.

### III. Overview

#### A. Background

**Transformer Architecture.** In this paper, we focus on the pruning of encoder-based Transformer [74] models, especially the BERT [11] architecture family. BERT is a stack of homogeneous Transformer encoder blocks, each of which consists of a multi-head attention (MHA) layer followed by a point-wise Feed-Forward Network (FFN) layer. Specifically, an MHA layer consists of $H$ independently parameterized attention heads:

$$
\text{MHA}(x) = \sum_{i=1}^{H} \text{Att}_i(x), \quad x_{\text{MHA}} = \text{LN}(x + \text{MHA}(x)),
$$

where Att is a dot product attention head, LN is layer normalization, and x is the input sequence. The output of the MHA layer is then fed into the FFN layer, which consists of $N$ filters:

$$
\text{FFN}(x) = \left( \sum_{i=1}^{N} W^{(2)}_{i,i} \sigma(W^{(1)}_{i,i} x + b^{(1)}_{i}) \right) + b^{(2)},
$$

$$
x_{\text{out}} = \text{LN}(x_{\text{MHA}} + \text{FFN}(x_{\text{MHA}})),
$$

where $W^{(1)}$, $W^{(2)}$, $b^{(1)}$ and $b^{(2)}$ are the FFN parameters, and $\sigma$ is the activation function, typically GELU [21]. Note that $(H, N)$ is (12, 3072) for BERT_{BASE}, and (16, 4096) for BERT_{LARGE}. We also denote $L$ as the number of Transformers layers.

**Granularity of Pruning and Notations.** Our framework considers the structured pruning of both heads in MHA and filters in FFN layers. We do not prune the embedding and the final classifier, as computation of those layers takes a negligible portion of the total inference latency. Since our pruning framework always produces a smaller dense architecture, the model can be readily accelerated without the need for specific hardware logic, which is often required to gain latency speedup for unstructured sparsity.

For mathematical simplicity, we introduce mask variables associated with the outputs of heads and filters:

$$
\text{MHA}(x; m^{\text{MHA}}_i) = \sum_{i=1}^{H} m^{\text{MHA}}_{l,i} \circ \text{Att}_i(x),
$$

$$
\text{FFN}(x; m^{\text{FFN}}_i) = \left( \sum_{i=1}^{N} m^{\text{FFN}}_{l,i} \circ W^{(2)}_{i,i} \sigma(W^{(1)}_{i,i} x + b^{(1)}_{i}) \right) + b^{(2)},
$$

where $m^{\text{MHA}}_i \in \mathbb{R}^H$ and $m^{\text{FFN}}_i \in \mathbb{R}^N$ are the mask variables for MHA and FFN in the $l$-th layer, respectively, and $m^{\text{MHA}}_{l,i}$ and $m^{\text{FFN}}_{l,i}$ are their $i$-th elements. Furthermore, $\circ$ denotes Hadamard product. Originally, the mask variables are initialized to 1. Zeroing out a mask variable is equivalent to pruning a head/filter associated with it. That is, setting $m^{\text{MHA}}_{l,i}$ and $m^{\text{MHA}}_{l,i}$ as zero is equivalent to pruning the $i$-th head and filter, respectively. This process is illustrated in Figure 2 (Top).

Overall, there are $HL$ head mask variables and $NL$ filter mask variables, summing up to $(H+N)L$ number of total mask variables in a Transformer model. To simplify notations, we additionally define $m^{\text{MHA}} \in \mathbb{R}^{HL}$, $m^{\text{FFN}} \in \mathbb{R}^{NL}$, and $m \in \mathbb{R}^{(H+N)L}$ as the flattened vectors of the head, filter, and total mask variables, respectively, across all layers. In what follows, we discuss how to find the optimal sparse masks under a given cost constraint and how to adjust their values to recover accuracy.

#### B. Framework Overview

Figure 1(b) and Figure 2 (Bottom) illustrate the overview of our framework.

**Inputs.** Our framework has 3 inputs: a Transformer model; a sample dataset; and a resource constraint. The input Transformer model should be fine-tuned for a downstream task. The sample dataset is a small portion of the training dataset (typically 1–2K examples) of the downstream task. The resource constraint can be given either as the number of floating point operations (FLOPs)
Fig. 2: (Top row) An overview of a pruned Transformer layer (residual connections and LayerNorms are omitted for simplicity) where the number of heads \((H)\) and filters \((N)\) are 3 and 4, respectively. The black entries indicate pruned heads and filters by zeroing out the associated mask variables. (Bottom row) Overview of our framework. (a) The mask variables are initialized as 1. Then they undergo the 3-stage pipeline of (b) mask search (Section IV-A), (c) rearrangement (Section IV-B), and (d) tuning (Section IV-C).

or as an actual latency on target hardware. In the later case, we further assume that a latency lookup table for the target hardware is provided.

**Compression Pipeline.** As illustrated in Figure 2, our framework consists of 3 stages: Fisher-based mask search; Fisher-based mask rearrangement; and mask tuning. During the Fisher-based mask search stage (Section IV-A), we search for a binary mask applied to the heads and filters by incorporating the Fisher information of the mask variables. Intuitively, the mask variables with relatively higher Fisher information are considered more important, and they should be less likely to be pruned [38, 42, 50]. As finding the optimal mask that minimizes the Fisher information loss is intractable using the full Fisher matrix, we propose a lightweight search algorithm that finds the optimal mask under reasonable approximations. Second, in the Fisher-based mask rearrangement stage (Section IV-B), the framework modifies the searched mask patterns in a layer-wise manner to better take into account the intra-layer interactions of the mask variables. Lastly, in the mask tuning stage (Section IV-C), the framework tunes the nonzero mask variables to recover the accuracy drop by reconstructing the layer-wise output signal.

**IV. METHODOLOGY**

We pose the pruning problem as finding a binary mask to zero out a particular head or filter. After finding the initial set of mask variables, we then allow adaptation/tuning of the remaining masks variables to avoid changes in the output norm of a layer. This process is done without any retraining of the model.

Note that the number of the mask variables is much less than the number of parameters in a Transformer (e.g., 37K vs. 110M in case of BERT\textsubscript{BASE}). This allows the framework to use only a small number of examples without overfitting to a sample dataset, and thus to be extremely fast compared to the retraining-based pruning methods which typically uses the entire training dataset. As the framework keeps the model “as is” and only decides the mask variables, we henceforth regard the model parameters as constants and consider the mask variables as the only parameters for our pruning problem.

**Problem Formulation.** We formulate Transformer pruning as a constrained optimization problem on the mask \(m\):

\[
\arg\min_m \mathcal{L}(m) \quad \text{s.t.} \quad \text{Cost}(m) \leq C
\]

where \(\mathcal{L}\) denotes the loss function, Cost is the FLOPs/latency of the architecture pruned by the mask, and \(C\) is the given FLOPs/latency constraint. Unfortunately, such a problem is generally intractable as Cost is usually a function of \(l_0\)-norm of the mask \(m\), which is non-differentiable. Thus, in what follows, we introduce several assumptions and approximations to simplify the problem.

We start by approximating the loss function using the second-order Taylor expansion around the initial mask \(\mathbb{1}\):

\[
\mathcal{L}(m) = \mathcal{L}(\mathbb{1} - (1 - m))
\]

\[
\approx \mathcal{L}(\mathbb{1}) - g^\top(1 - m) + \frac{1}{2}(1 - m)^\top H(1 - m)
\]

\[
\approx \mathcal{L}(\mathbb{1}) + \frac{1}{2}(1 - m)^\top H(1 - m),
\]

where \(g = \mathbb{E}[\frac{\partial}{\partial m} \mathcal{L}(1)]\) and \(H = \mathbb{E}[\frac{\partial^2}{\partial m^2} \mathcal{L}(1)]\). Eq. 4 is deduced from an assumption that the model has converged to a local minima, where the gradient term is close to 0 [38]. As \(\mathcal{L}(\mathbb{1})\) is a constant, we can rewrite the optimization objective as follows:

\[
\arg\min_m \mathcal{L}(m) \approx \arg\min_m (1 - m)^\top H(\mathbb{1} - m). \quad (5)
\]

Eq. 5 shows that the optimal mask is determined by the Hessian of the loss with respect to the mask variables. Since forming the exact Hessian matrix explicitly is infeasible, we approximate the Hessian \(H\) with the empirical Fisher information matrix \(\mathcal{I}\) of the mask variables:

\[
\mathcal{I} := \frac{1}{|\mathcal{D}|} \sum_{(x,y) \in \mathcal{D}} \left( \frac{\partial}{\partial m} \mathcal{L}(x,y;1) \right) \left( \frac{\partial}{\partial m} \mathcal{L}(x,y;1) \right)^\top,
\]

where \(\mathcal{D}\) is the training dataset.

**Algorithm.** We propose the following algorithm to find the optimal mask:

1. **Initial Mask:** Initialize the mask variables as \(m\) = \(\mathbb{1}\).
2. **Mask Search:** Use a search algorithm to find \(m^\star\) that minimizes \(\mathcal{L}(m^\star)\) subject to \(\text{Cost}(m^\star) \leq C\).
3. **Mask Rearrangement:** Rearrange the mask variables to account for the intra-layer interactions.
4. **Mask Tuning:** Tune the nonzero mask variables to recover the accuracy drop by reconstructing the layer-wise output signal.

We formulate our method using a second-order Taylor expansion and an approximate cost function subject to a latency constraint. This allows us to efficiently find the optimal mask within a small number of examples, without overfitting to a sampled dataset.

\textbf{Output:} $m^* = (m^{\text{MHA}}, m^{\text{FFN}})$

where $\mathcal{D}$ is the sample dataset and $(x, y)$ is a tuple of an input example and its label.

\textbf{A. Fisher-Based Mask Search}

Diagonal Approximation of Fisher Information Matrix. It is not straightforward to solve the optimization objective in Eq. 5 using the full empirical Fisher information matrix $\mathcal{I}$. Thus, we first make a simple assumption that $\mathcal{I}$ is diagonal. This further simplifies Eq. 5 as follows:

$$\arg \min_m \mathcal{L}(m) \approx \arg \min_m \sum_i (1 - m_i)2\mathcal{I}_{ii}, \quad (7)$$

Since we restrict the possible mask values to either 0 or 1, the following can be derived from Eq. 7:

$$\arg \min_m \mathcal{L}(m) \approx \arg \min_m \sum_{i \in Z(m)} \mathcal{I}_{ii}, \quad (8)$$

where $Z(m) := \{ i \mid m_i = 0 \}. \quad (9)$

We can interpret the diagonal element of $\mathcal{I}$ as the \textit{importance score} of the head/filter associated with each mask variable, and Eq. 8 as a process of minimizing the total importance scores of the pruned heads and filters. Such an importance score has also been introduced in [50, 72] to guide pruning.

Solving FLOPs-constrained Problem. We need to solve Eq. 8 given a cost constraint. For a given target FLOP cost, denoted by $C$, we can formulate the binary mask search problem as follows:

$$\arg \min_m \sum_{i \in Z(m)} \mathcal{I}_{ii}, \quad (10)$$

\text{ s.t. } F_{\text{head}}||m^{\text{MHA}}||_0 + F_{\text{filter}}||m^{\text{FFN}}||_0 \leq C, \quad (11)$$

where $F_{\text{head}} \in \mathbb{R}$ and $F_{\text{filter}} \in \mathbb{R}$ are the FLOPs for computing a head and a filter, respectively. Note that the number of FLOPs of a head/filter is constant across all layers. While such an optimization problem can be generally solved by a knapsack algorithm [1, 62], the following observations allow a simpler and faster solution: (1) having more heads and filters unpruned always optimizes Eq. 10 since the diagonal elements of $\mathcal{I}$ are non-negative; and (2) if a certain number of heads needs to be pruned, they should be the ones with the lowest importance scores because each head accounts for the same amount of FLOPs. The same statement also holds for pruning filters. These lead to our mask search algorithm described in Alg. 1.

Algorithm 1 partitions the solution space by the number of remaining heads in the pruned architecture ($n$ in line 1). For each $n$, by observation (1), the number of remaining neurons should be as line 4. Then by observation (2) the heads/filters with the lowest important scores are selected to be pruned. $S[\{n\}]$ is the evaluation of Eq. 10 with this mask. When the loop terminates, the output is the mask with the smallest $S[\{n\}]$. In Section A, we prove that the output mask $m^*$ of Algorithm 1 is optimal. That is, any other mask $m$ satisfying the given FLOPs constraint will have a higher loss:

$$\sum_{i \in Z(m^*)} \mathcal{I}_{ii} \leq \sum_{i \in Z(m)} \mathcal{I}_{ii}. \quad (12)$$

Solving Latency-constrained Problem. If the cost constraint is given in terms of actual latency on target hardware, we have a new cost constraint formula in the optimization target in Eq. 10:

$$\sum_{l=1}^L \text{LAT}(m^{\text{MHA}}) + \sum_{l=1}^L \text{LAT}(m^{\text{FFN}}) \leq C, \quad (13)$$

where the function LAT indicates the latency of a MHA/FFN layer after pruning. We assume that a latency lookup table on the target hardware is provided so that evaluating LAT takes very small overhead.

Unfortunately, the problem with a latency constraint is more challenging than the problem with a FLOPs constraint, and it cannot be solved by directly applying Algorithm 1. This is because LAT may not be linear to the number of remaining heads or filters after pruning [56], as shown in Figure 3 (Left). We can interpret this as follows: (1) with a sufficient number of heads/filters in a layer, the hardware resources such as parallel cores can be fully utilized, resulting in latency roughly proportional to the number of heads/filters; and (2) otherwise, the hardware resources are underutilized and a constant overhead dominates the latency [35, 47]. Thus, pruning
more heads/filters below a certain threshold does not translate into actual speedup.

Based on the above analysis, we approximate LAT as a piece-wise linear function as in Figure 3 (Right) such that LAT(m) is 0 if ||m||_0 = 0, c if 0 < ||m||_0 ≤ T, and a(||m||_0 − T) + c if ||m||_0 > T, where c ∈ ℝ is the constant overhead, T ∈ ℕ is the threshold number of heads/filters that the latency starts to be linear, and a ∈ ℝ is the slope of the linear part. This can be easily obtained by fitting the actual latency in the lookup table with the minimum mean squared error.

This LAT approximation allows us to extend Algorithm 1 to solving the problems with latency constraints. The core idea is to consider separately the constant part of LAT and the linear part of LAT; after handling the constant part, we can apply the Algorithm 1 to the linear part. This method guarantees the optimal solution for all cases only if we do not consider the case of pruning entire layers. As we observe that dropping an entire layer leads to significant accuracy drop without retraining, we believe our algorithm finds optimal solutions in most cases. The detailed modification to Algorithm 1 is described in Section B.

B. Fisher-based Mask Rearrangement

Block Diagonal Approximation of Fisher Information Matrix. Although it simplifies the problem, the diagonal assumption in Section IV-A alone might not find the best solution, as it does not take into account the interactions between different mask variables. We can capture the interactions by using a block diagonal approximation to the Fisher operator. Here a block corresponds to a MHA layer or a FFN layer. However, the block diagonal approximation results in a hard-to-optimize binary mask search problem. To alleviate this problem, we use the results from the previous step to warm start the optimization problem with the block-diagonal approximation. That is, given the mask m^* obtained in Section IV-A, we constrain ||m||_0 to be equal to ||m^*||_0 for all layers l.

Given the two assumptions, that (i) there is no interaction between the mask variables in different layers (i.e., the block diagonal approximation), and (ii) the number of pruned heads/filters are pre-determined for each layer (i.e., warm-start), Eq. 5 breaks down to a set of layer-wise optimization problems, as follows based on the derivation in Section C:

\[ \hat{m}_l = \arg \min_{m_l} (1 - m_l)^T \mathcal{I}_l (1 - m_l), \]

where \( \mathcal{I}_l \) is the l-th diagonal block of \( \mathcal{I} \). This can be approximately solved by greedily exploring the possible binary masks for \( m_l \) since ||m||_0 is fixed. In effect, this process rearranges the binary mask variables to find a better arrangement for pruning locations.

C. Mask Tuning

In the previous two stages, the possible mask values are restricted to either 0 or 1 in order to simplify the search process. In this stage, we further relax this restriction. The nonzero variables in the mask \( \hat{m} \) from Section IV-B are tuned to any real values such that the pruned model recovers its accuracy.

Layer-wise Reconstruction via Linear Least Squares. We tune the mask variables toward minimizing the layer-wise reconstruction error, similarly to [20]. For each layer, we reconstruct the output activation of the original model with the remaining heads/filters in the pruned model. This can be formally written as follows:

\[ \arg \min_{m_l} \| x + \text{layer}(x; m_l) - (x' + \text{layer}(x'; 1)) \|_2^2, \]

where layer is the either MHA or FFN, and x and x' are the inputs to the layer of the pruned model and the original model, respectively. Note that this stage does not incur any change in model FLOPs/latency, as we only tune the non-zero valued mask variables. We show in Section D that Eq. 15 is reduced to a linear least squares problem of \( \arg \min_{m_l} \| A m_l - b \|_2^2 \), where the matrix A denotes a collection of the output activations of the model pruned by the binary mask and the vector b is the output activation of the original model.

Because the size of the matrix A can be large, our framework uses the LSRM solver in CuPy [52] to solve the linear least squares problem. For the regularization hyperparameter (i.e., \( \text{damp} \)) of LSRM, we fix its value to 1. Then, to increase stability, we restrict the acceptable
range of the tuned mask variables to [-10, 10]. When the solver finds a layer mask that exceeds this range, we simply discard the mask for that layer and stop mask tuning. While the use of LSMR solver involves only two hyperparameters (i.e., damp and the acceptable mask range), we empirically find that these hyperparameters need not be tuned for different tasks and models. Consequently, our framework requires no user intervention in the pruning pipeline. In all of our experiments, we used the fixed hyperparameter values.

Teacher Assistant as Reconstruction Target. Mask tuning is analogous to knowledge distillation (KD) [22] in that a small model is optimized to mimic the behavior of a larger model. In the literature of KD, a well-known technique to bridge the gap between the student and the teacher is to introduce a teacher assistant (TA) [49], an intermediate-sized model that has comparable representation power to the teacher. Inspired by this, we find it effective to tune the mask variables by minimizing the reconstruction error against the intermediate representations of a TA, instead of those of the original model. In our framework, the TA is a moderately pruned model that is produced by the same search procedure in Section IV-A and Section IV-B. Specifically, when the target FLOPs/latency is $r$ (e.g., 0.64) times that of the original model, the framework searches for a TA model with $\sqrt{r}$ (i.e., 0.8) FLOPs/latency, and then uses it to tune the mask of the student. As the mask search and rearrangement stages can be processed in a few seconds once the mask gradients are computed, generating a TA from the original model takes negligible time (see Table IV).

V. Evaluation

A. Experimental Setup

Our framework is implemented on top of PyTorch [54] and HuggingFace Transformers [84] library. We evaluate the effectiveness of our approach using BERT$_{BASE}$ [11] and DistilBERT [60] on GLUE [76] and SQuAD [57, 58] benchmarks. We use 2K examples from the training sets for pruning, and we evaluate the resulting models on the development sets. All of the results are averaged over the runs with 10 different seeds. More details on the experimental setup can be found in Section E.

B. Performance Evaluation

FLOPs. Figure 4 shows the accuracy of BERT$_{BASE}$ and DistilBERT with different FLOPs constraints on GLUE and SQuAD datasets. As can be seen in the plots, with only 1% of accuracy drop, BERT$_{BASE}$ achieves 60–70% of the original FLOPs for all tasks. DistilBERT also shows a similar pattern and shows 50% FLOPs
Table I: Latency speedup of BERT$_{\text{BASE}}$ on an NVIDIA V100 GPU with different batch sizes. We constrain the accuracy degradation to be at most 1% from the baseline accuracy, and we report the largest speedup among those that satisfy the constraint.

</tbody>
</table>

Interestingly, our method exhibits comparable or sometimes better results than the prior methods without any model retraining and with substantially small pruning costs. This demonstrates empirically that retraining and a complex pruning pipeline is not necessary for moderate level of pruning of Transformers.

Retraining Cost. We select DynaBERT [23], EBERT [46], and Block Movement Pruning (BMP) [36] by the FLOPs-accuracy trade-off of BERT$_{\text{BASE}}$ on GLUE tasks. We use the results without knowledge distillation and data augmentation reported in each paper. Since the baseline accuracy differs slightly from paper to paper, we compare the amount of the accuracy drop from the baseline instead of the absolute accuracy. The results are plotted as Figure 5. We include the comparison details and full table in Section F.

C. Comparison with the Prior Methods

FLOPs and Accuracy Comparison. Here, we compare our method with the prior structured pruning methods for Transformers including Flop [81], SLIP [71], Sajjad et al. [59], DynaBERT [23], EBERT [46], and Block Movement Pruning (BMP) [36] that achieve comparably good accuracy in Figure 5, and we systematically analyze their end-to-end retraining costs on MNLI dataset. As shown in Table II, these methods require 5–17 hours of retraining. On the other hand, our method finishes in less than a minute, which is 2–3 orders of magnitude faster. We also highlight that this training latency only accounts for a single hyperparameter, and the entire cost should be multiplied by the size of the hyperparameter space. While the prior methods rely on a number of hy-

Unlike other methods (including ours) that take as input the fine-tuned models, Sajjad et al.\cite{59} starts from the pre-trained model, heuristically drops the top layers, and then fine-tunes on downstream tasks. Therefore, it can be regarded as a zero-cost pruning method. However, as can be seen in Figure 5, the resulting models suffer from large accuracy degradation in most cases.

D. Discussion

Ablation Studies. Table III lists an ablation of mask rearrangement (Section IV-B) and tuning (Section IV-C) stages for pruned BERT\textsubscript{BASE} with 60% of FLOPs. We find that both stages help recover the baseline accuracy, and that mask tuning is in particular critical, recovering up to 2.88% accuracy.

Time Breakdown. We break down our pruning pipeline into 4 parts—gradient computation, mask search, mask rearrangement, and mask tuning—and we measure the latency for each stage as Table IV. For GLUE and SQuAD tasks, our framework finishes in 39 and 135 seconds on average.

VI. Conclusion

In this work, we have proposed a novel post-training pruning framework for Transformers that does not require model retraining. The core of our framework is the three-stage pruning that recovers the accuracy without retraining. It uses a fast Fisher-based mask search algorithm to decide which heads/filters to prune, rearranges the pruned heads/filters, and tunes the mask variables to recover the output signal for each layer. We empirically evaluate our framework using BERT\textsubscript{BASE} and DistilBERT, where our pruning method achieves up to 50% FLOPs reduction with only 1% accuracy degradation on GLUE and SQuAD datasets. This results in up to 1.56× latency speedup on an NVIDIA V100 GPU. End-to-end pruning only needs 39 and 135 seconds for GLUE and SQuAD, which is 2–3 orders of magnitude faster than the prior methods. Overall, our method shows comparable or even better compression performance, as compared to the prior retraining-based methods.

Acknowledgments

We especially thank Suhong Moon for his fruitful feedback.

APPENDIX

A. Proof of Equation 12

We prove Eq. 12 by contradiction. Suppose that there exists a mask \( m \) such that

\[
\sum_{i \in Z(m)} I_{ii} < \sum_{i \in Z(m^*)} I_{ii},
\]

where the mask \( m^* \) is the output of Algorithm 1. Let \( h = ||m^{MHA}||_0 \), i.e. the total number of heads in the architecture pruned by the mask \( m \). Then we construct a new mask \( m' \) as follows:

1) Keep the mask for MHA layers. That is, \( m'^{MHA} = m^{MHA} \).
2) Construct \( m'^{FFN} \) as in the inner statements of the for loop (line 1 of Algorithm 1). That is, given a mask initialized to \( \mathbb{1} \), we zero out the \( k \) filter mask variables with the least important scores, where \( k = NL - [(C - f_{head})/f_{filter}] \).

Obviously, the mask \( m' \) satisfies the FLOPs constraint Eq. 11. Moreover, as the mask \( m' \) prunes the least important filters, the following two inequalities hold:

\[
\sum_{i \in Z(m')} I_{ii} = \sum_{i \in Z(m'^{MHA})} I_{ii} + \sum_{i \in Z(m'^{FFN})} I_{ii} \leq \sum_{i \in Z(m'^{MHA})} I_{ii} + \sum_{i \in Z(m'^{FFN})} I_{ii} \leq \sum_{i \in Z(m)} I_{ii}.
\]

Then we construct another mask \( m^* \) from \( m' \) such that:

1) Keep the mask for FFN layers. That is, \( m'^{FFN} = m'^{FFN} \).
2) Construct \( m'^{MHA} \) by zeroing out \( h \) head mask variables with the least important scores from a mask initialized to \( \mathbb{1} \).

Due to the observation (2) in Section IV-A, the following inequalities hold:

\[
\sum_{i \in Z(m^*)} I_{ii} \leq \sum_{i \in Z(m'^{MHA})} I_{ii} \leq \sum_{i \in Z(m'^{MHA})} I_{ii} + \sum_{i \in Z(m'^{FFN})} I_{ii} = \sum_{i \in Z(m')} I_{ii}.
\]

Essentially, \( m^* \) is the mask when \( n \) (in line 1 of Algorithm 1) is \( h \). As Algorithm 1 finds the minimum by iterating different values of \( n \), the following inequalities hold:

\[
\sum_{i \in Z(m^*)} I_{ii} \leq \sum_{i \in Z(m^*)} I_{ii}.
\]

Finally, the above inequalities are combined as follows:

\[
\sum_{i \in Z(m^*)} I_{ii} \leq \sum_{i \in Z(m^*)} I_{ii} \leq \sum_{i \in Z(m^*)} I_{ii} \leq \sum_{i \in Z(m)} I_{ii},
\]

which contradicts Eq. 16. Thus, the output mask \( m^* \) of Algorithm 1 is the minimizer of Eq. 10. \( \square \)

B. Latency-aware Search Algorithm

Algorithm 2 is our proposed algorithm for latency-aware mask search, which extends Algorithm 1. It takes as inputs the given latency constraint, approximated LAT functions for MHA and FFN layers, and the diagonal Fisher information matrix \( \mathcal{I} \). Overall, Algorithm 2 has the same structure as Algorithm 1. A notable difference between the two is that Algorithm 2 separately considers the constant part (i.e., when the number of heads/filters is below the threshold \( T \)) in line 1–5. Another difference is that Algorithm 2 uses \( d_{head} \) and \( d_{filter} \) instead of \( F_{head} \) and \( F_{filter} \) in Algorithm 1.
Algorithm 2 Mask Search with a Latency Constraint

Input: Latency constraint $C$, LAT function parameters $(\alpha_{\text{head}}, C_{\text{head}}, T_{\text{head}}), (\alpha_{\text{filter}}, C_{\text{filter}}, T_{\text{filter}})$, diagonal Fisher information matrix $\mathcal{I}$

1: $HI = \text{indices of most important heads in each layer}$
2: $FI = \text{indices of most important filters in each layer}$
3: $H' = H - T_{\text{head}}$
4: $N' = N - T_{\text{filter}}$
5: $C' = C - L(C_{\text{head}} + C_{\text{filter}})$
6: for $n = 0$ to $H'/L$ do
7:   $I = \text{indices of } n \text{ most important heads not in } HI$
8:   $f = [(C' - n\alpha_{\text{head}})/\alpha_{\text{filter}}]$  
9:   $J = \text{indices of } f \text{ most important filters not in } FI$
10: $HI' = HI \cup I$
11: $FI' = FI \cup J$
12: $S[n] = \sum_{i \in HI', \beta_{Ii}} \mathcal{I}_{ii}$
13: $R[n] = (HI', FI')$
14: end for
15: $n^* = \arg \max_n S[n]$
16: $HI^*, FI^* = R[n^*]$
17: Initialize $m_{\text{MHA}}$ and $m_{\text{FFN}}$ as 0
18: $m_{\text{MHA}}[HI^*] = 1$
19: $m_{\text{FFN}}[FI^*] = 1$
Output: $m^* = (m_{\text{MHA}}, m_{\text{FFN}})$

C. Derivation of Equation 14

Based on Eq. 6 and the warm-start constraint in Section IV-B, the optimization problem Eq. 5 is written as follows:

$$\arg \min_m (I - m)^\top \mathcal{I} (I - m),$$

subject to $||m_l||_0 = ||m^*_l||_0$ for $l = 1, 2, \ldots, L,$

$$\text{(24)}$$

where $m^*$ is the mask searched in Section IV-A using the diagonal approximation of $\mathcal{I}$. Under the block diagonal assumption, Eq. 23 can be reduced as follows:

$$\arg \min_m (I - m)^\top \mathcal{I} (I - m) \approx \arg \min_m \sum_{l=1}^L (I - m_l)^\top \mathcal{I}_l (I - m_l),$$

$$\text{(25)}$$

where $\mathcal{I}_l$ is the $l$-th diagonal block of $\mathcal{I}$. Here what we want to show is that the problem Eq. 25 can be solved by independently solving the optimization problem Eq. 14 for each layer. We prove this by contradiction. Suppose that $\hat{m} = (\hat{m}_1, \ldots, \hat{m}_L)$ is the mask obtained by solving Eq. 14 for each layer. If there exists a mask $m$ that strictly better optimizes Eq. 25 than $\hat{m}$:

$$\sum_{l=1}^L (1 - m_l)^\top \mathcal{I}_l (1 - m_l) < \sum_{l=1}^L (1 - \hat{m}_l)^\top \mathcal{I}_l (1 - \hat{m}_l),$$

$$\text{(26)}$$

while also satisfying the constraint Eq. 24, then there must exist a layer $k$ such that

$$(1 - m_k)^\top \mathcal{I}_k (1 - m_k) < (1 - \hat{m}_k)^\top \mathcal{I}_k (1 - \hat{m}_k).$$

$$\text{(27)}$$

However, this contradicts the assumption that $\hat{m}_k$ is the minimizer of Eq. 14 for layer $k$. Therefore, such a mask as $m$ cannot exist, and $\hat{m}_k$ is the optimal solution for Eq. 25.

D. Formulating Equation 15 as a Linear Least Squares Problem

For an MHA layer, the problem of minimizing reconstruction error can be written as follows:

$$\arg \min_{m^*_{\text{MHA}}} ||(x + \text{MHA}(x; m^*_{\text{MHA}})) - (x' + \text{MHA}(x'; 1))||_2^2,$$

subject to $Z(m^*_{\text{MHA}}) = Z(\hat{m}^*_{\text{MHA}}),$
where \( \hat{m} \) is the mask obtained as the result of mask rearrangement (Section IV-B). Eq. 29 is the constraint we impose in Section IV-C that the zero-valued mask variables in \( \hat{m} \) are fixed to 0 so that the tuned mask also satisfies the FLOPs/latency constraint. Then we rewrite the problem as the following linear least squares problem:

\[
\arg \min_{\hat{m}} ||A\hat{m} - b||^2_2, \tag{30}
\]

where \( A := [\hat{m}^{\text{MHA}}_{l, 1} \text{Att}_1(x), \ldots, \hat{m}^{\text{MHA}}_{l, H} \text{Att}_H(x)] \) and \( b := (x' + \sum_{h=1}^H \text{Att}_h(x')) - x. \tag{31} \)

Here, the elements of \( \hat{m}^{\text{MHA}}_l \) are multiplied to the matrix \( A \) to ensure that the output activations of the pruned heads are not used to reconstruct the original output. Although Eq. 30 has a closed form solution \((A^\top A)^{-1}A^\top B\), we use the numerical solver in CuPy for higher stability.

E. Experimental Details

1) Experimental Setup: Our framework is implemented on top of PyTorch v1.9.1 [54] and HuggingFace Transformers v4.12.0 [84]. For the baseline, we downloaded the pre-trained checkpoints from the HuggingFace Transformers repository, and we fine-tuned them on GLUE [76] and SQuAD [57, 58] datasets with the standard training recipe. We then use 2K examples from the training sets to prune the baseline models. We report accuracy for GLUE tasks, except for STS-B that we report Spearman Correlation, and F1 score for SQuAD tasks on the development sets. All experiments in this paper are conducted on an AWS p3.2xlarge instance which has an NVIDIA V100 GPU. We used seed numbers from 0 to 9, and we reported the averaged results.

2) Datasets: GLUE tasks [76] include sentence similarity (QQP [29], MRPC [12], STS-B [5]), sentiment classification (SST-2 [66]), textual entailment (RTE [10]) and natural language inference (MNLI [83], QNLI [58]). There are 364K, 4K, 6K, 67K, 3K, 392K, 105K training examples, respectively. We exclude CoLA [82] and WLNI [39] due to their unstable behaviors.

SQuAD 1.1 [58] and SQuAD 2.0 [57] are question and answering tasks, each of which contains 88K and 130K training examples. SQuAD 2.0 is an extension of SQuAD 1.1 by including unanswerable questions whose answers are not stated in the given contexts.

F. Details for the Comparison with the Prior Methods

We compare the FLOPs-accuracy trade-off of our method to the prior structured pruning methods for Transformers in Flop [81], SLIP [71], Sajjad et al. [59], DynaBERT [23], EBERT [46], and Block Movement Pruning (BMP) [36] on 4 GLUE tasks, QQP, QNLI, SST-2, and MRPC. We use the FLOPs and accuracy values reported in each paper (for Flop, we use the values reported in SLIP). To make a fair comparison, we use the experimental results without any additional knowledge distillation or data augmentation in each paper. Because all of these papers have slight differences in their baseline accuracy, it is difficult to directly compare the absolute accuracy for the pruned models. Therefore, we use the amount of the accuracy drop (i.e., accuracy of the pruned model subtracted by the accuracy of the original model) instead. For Flop and SLIP, the results for MRPC are reported as F1 score instead of accuracy. For these cases, we report that the amount of the F1 score drop instead, assuming that it is similar to the amount of the accuracy drop. Since BMP only reports the parameter counts reduction, we directly use this value as FLOPs reduction, under an assumption that the head pruning ratio is similar to the filter pruning ratio. We include the full table in Table V.

G. Retraining Costs

DynaBERT [23] consists of 2-stage training, 1 epoch of width and depth-adaptive training followed by additional 3 epochs of final fine-tuning. For the first stage, it jointly trains 12 different width and depth configurations, roughly adding up 12× training costs than the normal training. EBERT [46] consists of 2-stage training, 3 epochs that jointly trains the pruning parameters and the model weights, followed by 3 additional epochs of final fine-tuning. BMP [36] requires 20 epochs of training to search for the optimal pruning configuration and retrain the model weights. We measure end-to-end retraining latency on an NVIDIA V100 GPU using a batch size of 32 for all experiments.
Table V: The absolute accuracy and the amount of accuracy degradation from the baseline after pruning BERT\textsubscript{BASE} using our method and the prior structured pruning methods with different relative FLOPs. †Reported as F1 score instead of accuracy.
