(Dated: April 22, 2022)

Intercellular signaling has an important role in organism development, but not all communication occurs using the same mechanism. Here, we analyze the energy efficiency of intercellular signaling by two canonical mechanisms: diffusion of signaling molecules and direct transport mediated by signaling cellular protrusions. We show that efficient contact formation for direct transport can be established by an optimal rate of projecting protrusions, which depends on the availability of information about the location of the target cell. The optimal projection rate also depends on how signaling molecules are transported along the protrusion, in particular the ratio of the energy cost for contact formation and molecule synthesis. Also, we compare the efficiency of the two signaling mechanisms, under various model parameters. We find that the direct transport is favored over the diffusion when transporting a large amount of signaling molecules. There is a critical number of signaling molecules at which the efficiency of the two mechanisms are the same. The critical number is small when the distance between cells is far, which helps explain why protrusion-based mechanisms are observed in long-range cellular communications.

I. INTRODUCTION

Intercellular communication is crucial for maintenance and response to the external environment, allowing development, growth, and immunity. However, not all biological communication systems transport signals by the same mechanism. One well-known mechanism is simple diffusion, in which signaling molecules are produced by localized source cells and diffuse through extracellular space before degradation [1]. An alternative mechanism, called direct transport (DT), involves signaling molecules that are transported along protrusions [2] such as cytonemes [3–5], tunneling nanotubes [6], and airinemes [7]. One natural question is under what condition cells should be expected to utilize one or the other mechanism of signaling.

One or the other mechanism may be selectively favored, over evolution, by achieving better performance. In the scale of communication between two cells, first passage time of a signaling molecule to the target can be minimized by parallel search with multiple copies (called “redundancy principle”) [8, 9], which characterizes the fertilization process. This also can be achieved by resetting and repeating the search, which limits the search perimeter [10–12]. At a larger spatial scale with multiple cells, a concentration gradient of signaling molecules can be established in a short time [13–16], which is robust to parameter variation [13, 14] and internal noise [15], and even precise under a noisy environment [17]. However, there are only a few direct theoretic analyses comparing these two fundamentally different mechanisms of signaling (direct transport and diffusion), and most such studies focus on the formation of a concentration gradient [16, 17].

One crucial aspect for the fitness of cells and organisms is energy efficiency. Two significant sources of energy cost are synthesis of signaling molecules and polymerization of cellular protrusions. Synthesis cost depends on how many diffusive molecules released from the source cell successfully arrive at the target [18, 19]. DT involves the polymerization cost that is determined by the total number of polymerization events until protrusions make a contact to the target, which is characterized by the total elongation length of protrusions [20, 21]. However, the energy cost of intercellular signaling processes has not been considered much in modeling studies, as most such studies focus on the diffusion process, which does not require energy input once it is synthesized. In contrast to the diffusion model, DT requires energy costs for contact formation. And yet, once established, a protrusion can securely transport signaling molecules. One natural question is which mechanism, under different parameters values, will be more energetically efficient in total.

FIG. 1. Schematic figure of two intracellular transport mechanisms. (a) Direct transport (DT) mediated by protrusions. (b) Diffusion and degradation of signaling molecules.
In this paper, we investigate how a two-cell communication mechanism is optimized by balancing performance (transport time) and energy efficiency. We first find the optimal conditions within the direct transport model by minimizing the utility functions associated with the initiation rate of protrusion \( \kappa_{\text{DT}} \). If the protrusion initiation is frequent, then a cell can establish a contact quickly but it may waste energy due to excessive polymerization. Moreover, the optimal initiation rate depends on the number of signaling particles \( V \) required to be transported. This relationship is non-trivial because the effective diffusive transport along finite 1D domain varies with \( V \). We show how the relationship changes with the energy consumption rate of polymerization and synthesis of particles. Additionally, we study how spatial information about the target cell can help form a protrusion contact in a shorter time with less energy cost. Finally, we study the effect of protrusion length, which, if short, may save polymerization cost but is also less likely to hit the target. Similar optimality considerations for protrusion length has been studied in other directional search process with resetting [11, 12].

Next, we determine which one of the two models (direct transport or diffusion) is optimal for a given condition, by comparing the values of utility functions. One crucial variable for comparison is the number of transporting particles \( V \). At small \( V \), the diffusion model is generally preferable because it does not require additional energy cost for contact formation. At large \( V \), the direct transport model is preferable because the contact formation cost per particle is cheaper. We determine the critical number \( V_c \) such that the utility of the two models are the same, which can be a criterion for determining which model is preferable.

The structure of the paper is as follows. In Sect. II we introduce a direct transport model that combines the directional search model with resetting [12, 15] and particle transport model along 1D protrusions [13, 14], as illustrated in Fig. 1(a). We introduce two types of idealized targets, a disk and annulus in two dimensions, for analytic simplicity. We describe a single protrusion search event and then develop a process with multiple search events generated by a Poisson process with the initiation rate \( \kappa_{\text{DT}} \) until contact with the target is formed. We introduce a rare-event approximation of the stochastic contact formation process for analytic simplicity, and find relative error bounds. We then quantify the transport time for a required number of diffusive particles along the one-dimensional established protrusion. In Sect. III we introduce the “impatient” diffusive model (or diffusive particles with degradation), as depicted in Fig. 1(b), and we calculate the hitting probability and the transport time similar to previous section. In Sect. IV we define utility functions in terms of performance and energy cost (a cost-benefit ratio and a total energetic cost as a sum of the variables). We first investigate the behavior of the cost-benefit ratio for contact formation alone, and we establish the existence of an optimal initiation rate.

We then include the process of particle transport along an established protrusion, and we compare the optimal projection rate with and without the particle transport. Finally, we compare the cost-benefit ratio of DT versus impatient diffusion, and we quantify the critical number of signaling molecules that determines which mechanism has more utility. Most of our qualitative results are extended in the case of the total energetic cost. Statistics of a single protrusion search event for the ideal targets are calculated in Appendix. A. The hitting probability and the transport time of the diffusion model for the ideal targets are calculated in Appendix. B.

II. DIRECT TRANSPORT VIA PROTRUSIONS

A. Single protrusion event

Consider a source that extends a protrusion to find target \( \Omega \), as illustrated in Fig. 2(a). The protrusion is projected by a random angle \( \Theta \) with speed \( v_+ \). It grows until to a random protrusion length, \( L \), or hits the target. If the protrusion fails to hit the target, then it retracts to the source with speed \( v_- \).

We first study the contact probability \( \rho_{\text{DT}} \) that the protrusion will hit the target. The protrusion makes a contact to the target under the following conditions: (i) projection angle \( \Theta \) requires to be subtended by the target.
get with respect to the source, and this set of angles is denoted by \( \phi(\Omega) \); (ii) the protrusion length \( L \) must not be shorter than target distance \( \zeta(\Theta) \) at angle \( \Theta \). Introducing the effective target distance from the source

\[
Z = \begin{cases} 
\zeta(\Theta), & \Theta \in \phi(\Omega) \\
\infty, & \Theta \notin \phi(\Omega)
\end{cases}
\]

then the hitting probability takes the form of

\[
\rho_{\text{DT}} = P[Z \leq L].
\] (II.1)

Another important quantity is the conditional mean effective protrusion length (MEPL), conditioned on either hitting the target or not. The protrusion grows by protrusion length \( L \) or the target distance if hitting the target. Thus, the effective protrusion length (EPL) for each protrusion length satisfies

\[
X = \begin{cases} 
X_{\text{hit}}, & Z \leq L \\
X_{\text{miss}}, & Z > L
\end{cases},
\]

where \( X_{\text{hit}} = Z \) and \( X_{\text{miss}} = L \). This gives the conditional MEPL for hitting the target

\[
\lambda_{\text{hit}} = E[X_{\text{hit}}] = E[Z|Z \leq L],
\] (II.2)

and for missing the target

\[
\lambda_{\text{miss}} = E[X_{\text{miss}}] = E[L|Z > L].
\] (II.3)

The unconditional MEPL regardless of target contact is

\[
\lambda_0 = E[X] = \rho_{\text{DT}}\lambda_{\text{hit}} + (1 - \rho_{\text{DT}})\lambda_{\text{miss}}.
\] (II.4)

Moreover, one can also determine the protrusion travel time (PVT) in terms of EPL. Since the protrusion growth and shrinkage speed is assumed to be constant, then PT can be written by

\[
T_{\text{hit}} = \frac{X_{\text{hit}}}{v_+}, \quad T_{\text{miss}} = \left(\frac{1}{v_+} + \frac{1}{v_-}\right)X_{\text{miss}}.
\]

This yields the conditional MPVT

\[
\tau_{\text{hit}} = \frac{\lambda_{\text{hit}}}{v_+}, \quad \tau_{\text{miss}} = \left(\frac{1}{v_+} + \frac{1}{v_-}\right)\lambda_{\text{miss}}.
\] (II.5)

To compute the statistics of a single protrusion event, we introduce assumptions about target and the random variables, as depicted in Fig. 2(b). We consider two types of idealized targets: (i) a disk with minimum distance \( d \) and radius \( r \) and (ii) an annulus with minimum distance \( d \). We assume that protrusion length \( L \) follows an exponential distribution with mean \( \lambda_L \), i.e. its distribution takes the form of

\[
\rho_L(x) = \frac{1}{\lambda_L} e^{-x/\lambda_L},
\]

and protrusion angle \( \Theta \) follows a uniform distribution with base \( 2\sigma \)

\[
\rho_{\Theta}(x) = \frac{1}{2\sigma} \mathbb{I}_{[-\sigma,\sigma]}(x).
\]

Here \( \mathbb{I}_A(x) \) is the indicator function equal to one if \( x \in A \), otherwise zero; and \( \Theta = 0 \) is set to be the direction of the center of the disk, in the case of disk-type target. Computation of the hitting probability and the MEPLs for two idealized targets are presented in Appendix A.

**B. Contact formation via multiple protrusion events**

Next, we consider the search process via multiple protrusion events, separated by time intervals that are exponentially distributed with rate \( \kappa_{\text{DT}} \), as depicted in Fig. 3. More precisely, let \( P_k \) be the \( k \)th projection time and the corresponding inter-projection times are

\[
S_k = P_k - P_{k-1}, \quad S_1 = P_1,
\]

for \( k = 1, 2, \cdots \). Here \( S_k \) are independent and identically distributed exponential times with rate \( \kappa_{\text{DT}} \). The corresponding protrusion event is determined by the pair of the effective target distance and the protrusion length \( (Z_k, L_k) \). Let \( H_k \) denote the target arrival time of the \( k \)th projected protrusion. If it hits the target, then we have

\[
H_k = P_k + T_{\text{hit},k} = P_k + \frac{Z_k}{v_+}.
\]

Otherwise, \( H_k = \infty \).

To determine the overall speed of the target searching process, we are interested in the first passage time (FPT) of protrusions to the target, which takes the form of

\[
T_{\text{DT}} = \inf_{k \in K} \{H_k\},
\]

FIG. 3. Multiple protrusion events. Source cell projects multiple protrusions at time \( P_k \) for \( k = 1, 2, \cdots \) with exponential inter-projection times \( S_k = P_k - P_{k-1} \) at rate \( \kappa_{\text{DT}} \) until the first passage time to the target (FPT) \( T_{\text{DT}} \). Each protrusion grows to effective length (EPL) \( X_k \) for \( k = 1, 2, \cdots \) and the total effective protrusion length (TEPL) until the FPT is \( L_{\text{DT}} = \sum_k P_k \leq T_{\text{DT}} X_k \).
where $\mathcal{K} = \{k : Z_k \leq L_k\}$ is the set of indices for hitting events. We also compute the total effective protrusion length (TEPL) until the FPT to determine the energy cost for the protrusion polymerization. We introduce the random variable $N = \max\{ k : P_k \leq T_{DT}\}$, which represents the total number of protrusions until the FPT. Then TEPL can then be defined by

$$L_{DT} = \sum_{k=1}^{N} X_k.$$  

Note that $H_k$ is not necessarily an increasing sequence for $k \in \mathcal{K}$. In other words, even if one protrusion is projected earlier than others that hit the target, it might nonetheless arrive at the target later. Moreover, $L_{DT}$ depends on the non-trivial random variable $T_{DT}$. This makes the analysis quite involved, which motivates us to find approximations of these random variables.

### C. Rare-event approximation

We approximate the important random variables $T_{DT}$ and $L_{DT}$ by the rare-event approximation. In general, $H_k$ is not increasing sequence for $k \in \mathcal{K}$, but it is very unlikely that the protrusion projected later hits the target earlier than the protrusion projected earlier, as depicted in Fig. 4(a). Thus, we make the approximation that $H_k$ is increasing. Note that this approximation is exact when the EPL for hitting target has zero variance, in which case the rare event we neglect actually has zero probability. One example is that the source is surrounded by the target with the same distance. In general, the rare-event approximation overestimates the FPT and so does the TEPL

$$T_{DT} \leq \tilde{T}_{DT}, \quad L_{DT} \leq \tilde{L}_{DT}, \quad (\text{II.6})$$

due to the way of approximation. The important advantage of this rare-event approximation is that it provides analytical tractability. In this section, we calculate the first moment of the rare-event approximation of FPT and TEPL. Then we perform error estimation of the rare-event approximation.

We first calculate the rare-event approximation of the mean first passage time (MFPT) by applying the total expectation theorem $[15]$. Denoting $K_0 = \min \mathcal{K}$, then the FPT can be approximated by

$$T_{DT} \simeq H_{K_0} := \tilde{T}_{DT},$$

and the equality holds if $\text{Var}[X_{hit}] = 0$. Conditioning on $K_0 = j$ gives

$$\tilde{T}_{DT,j} = \mathbb{E}[\tilde{T}_{DT}|K_0 = j] = \mathbb{E} \left[ \sum_{k=1}^{j} S_k + T_{hit,j} \right].$$

Since $T_{hit,j}$ is independent of $j$, the conditional mean becomes

$$\tilde{T}_{DT,j} = \frac{j}{\kappa_{DT}} + \tau_{hit}. \quad (\text{II.7})$$

Using the total expectation theorem yields

$$\tilde{T}_{DT} = \mathbb{E}[\tilde{T}_{DT}|K_0 = j] = \sum_{j=1}^{\infty} \tilde{T}_{DT,j} \cdot \mathbb{P}[K_0 = j] = \sum_{j=1}^{\infty} \tilde{T}_{DT,j} \rho_{DT} (1 - \rho_{DT})^{j-1}.$$  

Substituting Eq. (II.7) we finally have the rare-event approximation of MFPT

$$\tilde{T}_{DT} = \frac{1}{\kappa_{DT} \rho_{DT}} + \tau_{hit}. \quad (\text{II.8})$$

This can be interpreted as the sum of the first protrusion time that hits the target $(\kappa_{DT}^{-1} \rho_{DT}^{-1})$ and the protrusion travel time to the target $(\tau_{hit})$.

Similarly, we calculate the rare-event approximation of the mean total number of protrusions

$$N \simeq K_0 + N_0(T_{hit,K_0}) := \tilde{N},$$

where $N_0(t)$ is the number of protrusions over time $t$. In order to get the mean number of protrusion, we apply renewal theory $[15, 22]$. We consider $N_0(t)$ as a renewal process with jumping time $P_k$ and jumping size one for $k = 1, 2, \cdots$, which takes the form

$$N_0(t) = \sum_{k} \mathbb{I}_{[0,\infty)}(t - P_k).$$
Conditioning the first jump time by setting $P_1 = y$, we have
\[
\mathcal{N}_0(t) = \begin{cases} 0, & t < y \\ 1 + \mathcal{N}_0(t - y), & t \geq y \end{cases}
\]
where $\mathcal{N}_0(t)$ has the same distribution as $\mathcal{N}_0(t)$. One can calculate the mean number of protrusions by applying the total expectation theorem
\[
\nu_0(t) = \mathbb{E}[\mathcal{N}_0(t)] = \mathbb{E} \left[ \mathbb{E}[\mathcal{N}_0(t) | P_1 = y] \right] = \int_0^t (1 + \nu(t - y)) \kappa_{\text{DT}} e^{-\kappa_{\text{DT}} y} dy. \tag{II.9}
\]
In order to solve the integral equation, we take the Laplace transformation over time
\[
\tilde{\nu}_0(s) = \left( \frac{1}{s} + \tilde{\nu}_0(s) \right) \frac{\kappa_{\text{DT}}}{s + \kappa_{\text{DT}}}, \tag{II.10}
\]
to deduce that $\tilde{\nu}_0(s) = \kappa_{\text{DT}} s^{-2}$. It follows that
\[
\nu_0(t) = \kappa_{\text{DT}} t. \tag{II.11}
\]
In the same fashion, we next calculate the rare-event approximation of mean total effective protrusion length (MTEPL)
\[
\mathcal{L}_{\text{DT}} \simeq \sum_{k=1}^{\mathcal{N}_0} X_k := \bar{\mathcal{L}}_{\text{DT}},
\]
which also can be written by
\[
\bar{\mathcal{L}}_{\text{DT}} = \sum_{k=1}^{K_0} X_k + \sum_{k=K_0+1}^{K_0+N_0(\text{hit},K_0)} X_k, \tag{II.12}
\]
where $X_k = X_{\text{miss},k}$ if $k < K_0$ and $X_{K_0} = X_{\text{hit},K_0}$. Since $K_0$ and $X_{\text{hit},K_0}$ are independent we condition the expectation by setting $K_0 = j$ and $X_{\text{hit},K_0} = x$
\[
\tilde{\lambda}_{\text{DT},j}(x) = \mathbb{E}[\bar{\mathcal{L}}_{\text{DT}} | K_0 = j, X_{\text{hit},K_0} = x] = (j - 1) \lambda_{\text{miss}} + x + \mathbb{E} \left[ \sum_{k=1}^{N_0(x/v_+)} X_k \right].
\]
Using the independence of $\mathcal{N}_0(x)$ and $X_k$ for $k > j$, we have
\[
\mathbb{E} \left[ \sum_{k=1}^{N_0(x/v_+)} X_k \right] = \mathbb{E}[\mathcal{N}_0(x/v_+)] \mathbb{E}[X_k] = \frac{\kappa_{\text{DT}} x \lambda_0}{v_+}, \tag{II.13}
\]
by substituting Eq. (II.11). Thus, the unconditional expectation satisfies
\[
\tilde{\lambda}_{\text{DT}} = \mathbb{E} \left[ \mathcal{L}_{\text{DT}} | K_0 = j, X_{\text{hit},K_0} = x \right] = \sum_{j=1}^{\infty} \tilde{\lambda}_{\text{DT},j}(\lambda_{\text{hit}}) \rho_{\text{DT}} (1 - \rho_{\text{DT}})^{j-1} \]
\[
= (\rho_{\text{DT}}^{-1} - 1) \lambda_{\text{miss}} + \lambda_{\text{hit}} + \kappa_{\text{DT}} \tau_{\text{hit}} \lambda_0, \tag{II.14}
\]
which can be simplified as
\[
\tilde{\lambda}_{\text{DT}} = \kappa_{\text{DT}} \tilde{\tau}_{\text{DT}} \lambda_0. \tag{II.15}
\]

Fig. 5 shows that the rare approximation mean has good agreement with the MFPT and the MTEPL estimated by the Monte Carlo simulations. Moreover, the direct contact can be formed in shorter time by generating more protrusions as the projection rate increases. However, the asymptotic MFPT never goes to zero, instead, it converges to
\[
\lim_{\kappa_{\text{DT}} \to \infty} \tau_{\text{DT}}(\kappa_{\text{DT}}) = \frac{d}{v_+}, \tag{II.16}
\]
which is the traveling time along the minimum distance (geodesic), as suggested in [23, 24].

One natural question is how close the rare-event approximation is to the exact process. We address this issue by determining an error bound for a particular shape of target, a disk. Consider a target disk with radius $r$ and minimum distance $d$ from the source. To determine a lower bound, we introduce a "polar rectangle" $\hat{\Omega}$ containing the disk $\Omega$, as depicted in Fig. 4(b). Then the effective target distance of $\hat{\Omega}$ is shorter than $\Omega$ for given angle
\[
\zeta(\Theta; \Omega) \geq \zeta(\Theta; \hat{\Omega}) = d,
\]
and the set of subtended angle with respect to the target set satisfies
\[
\phi(\Omega) \subset \phi(\hat{\Omega}).
\]
These conditions show that the hitting probability of a single protrusion event to $\Omega$ is larger than $\Omega$ and shorter than the conditional hitting time

$$\rho_{\text{DT}}(\Omega) \leq \rho_{\text{DT}}(\Omega), \quad \tau_{\text{hit}}(\Omega) \geq \tau_{\text{hit}}(\Omega),$$

which also guarantees that

$$\bar{\tau}_{\text{DT}}(\Omega) \leq \bar{\tau}_{\text{DT}}(\Omega),$$

for the same sequence of random pairs $(\Theta_k, L_k)$ for $k = 1, 2, \ldots$. Since $T_{\text{hit}}(\Omega) = d$ and $\text{Var}[T_{\text{hit}}(\Omega)] = 0$, we have

$$\tau_{\text{DT}}(\Omega) = \bar{\tau}_{\text{DT}}(\Omega).$$

Together with Eqs. (II.6) and (II.18), we have the error bound of the rare-event approximation

$$|\bar{\tau}_{\text{DT}}(\Omega) - \tau_{\text{DT}}(\Omega)| \leq \delta[\bar{\tau}_{\text{DT}}],$$

where $\delta[f] = f(\Omega) - f(\tilde{\Omega})$ and

$$\delta[\bar{\tau}_{\text{DT}}] = \frac{\delta[\rho_{\text{DT}}^{-1}]}{\kappa_{\text{DT}}} + \frac{\delta[\lambda_{\text{hit}}]}{v_{+}},$$

in accordance with Eq. (II.8). Moreover, the relative difference satisfies

$$\frac{\delta[\bar{\tau}_{\text{DT}}]}{\bar{\tau}_{\text{DT}}(\Omega)} \leq \frac{\delta[\rho_{\text{DT}}^{-1}]}{\rho_{\text{DT}}^{-1}(\Omega)} + \frac{\delta[\lambda_{\text{hit}}]}{\lambda_{\text{hit}}(\Omega)} \leq 1 - e^{-\tau_{\text{hit}}/\lambda_{\text{hit}}} + \frac{r}{r + \lambda_{\text{hit}}}$$

in terms of the model parameters. Details of derivation can be found in Appendix A. This inequality implies that the relative error is smaller if the target is smaller and farther from the source. That is, the rare-event approximation is accurate if it is hard to hit the target in a single protrusion. Similarly, one can derive the error bound for the MTEPL

$$|\bar{\lambda}_{\text{DT}}(\Omega) - \lambda_{\text{DT}}(\Omega)| \leq \delta[\bar{\lambda}_{\text{DT}}] = \kappa_{\text{DT}} \lambda_0 \delta[\bar{\tau}_{\text{DT}}],$$

which has the same relative bound in Eq. (II.22).

**D. Particle transport along protrusion**

Once a protrusion makes a contact with length $X_{\text{hit}}$, we assume that the source begins to produce signaling molecules with rate $\kappa$, as depicted in Fig. 6(a). These particles move along the protrusion via diffusion and they are absorbed at the target. Since the protrusion is a thin and long filament, we treat this process as a one-dimensional diffusion. We now determine the transport time $\psi_{\text{DT}}$ for delivering a required number of signaling molecules, $V$.

More precisely, let $u(x, t)$ denote the molecule concentration along the protrusion for $0 < x < X_{\text{hit}}$, which evolves according to

$$\frac{\partial u}{\partial t} = D \frac{\partial^2 u}{\partial x^2},$$

where $D$ is the diffusion coefficient along a protrusion. Here we assume that the molecules are not degraded while they move within the protrusion, because diffusion along the protrusion is relatively stable compared to the outer environment. This equation is supplemented by the boundary conditions

$$-D \frac{\partial u(0, t)}{\partial x} = \kappa, \quad u(X_{\text{hit}}, t) = 0.$$  

Then the flux at position $x$ takes the form of

$$J_{\text{DT}}(x, t) = -D \frac{\partial u(x, t)}{\partial x}.$$  

The transport time $\psi_{\text{DT}}(V; X_{\text{hit}})$ for given protrusion length $X_{\text{hit}}$ and required number of particles $V$ satisfies the following integral equation

$$\int_0^{\psi_{\text{DT}}} J_{\text{DT}}(X_{\text{hit}}, t') dt' = V,$$  

which yields the mean particle transport time with respect to the protrusion length

$$\psi_{\text{DT}}(V) = E[\psi_{\text{DT}}(V; X_{\text{hit}})].$$

Numerically computing the mean particle transport time can be complex because $X_{\text{hit}}$ is implicitly involved in the expression. We address this issue by introducing the non-dimensional variables $x_0 = x/X_{\text{hit}}$, $t_0 = tD/X_{\text{hit}}^2$, $V_0 = VD/(\kappa X_{\text{hit}}^2)$, and $J_{\text{DT},0} = J_{\text{DT}}/\kappa$. The integral equation (II.26) can then be written by

$$\Psi_{\text{DT}}(\psi_{\text{DT},0}) := \int_0^{\psi_{\text{DT},0}} J_{\text{DT},0}(t_0') dt_0' = V_0,$$  

where $\Psi_{\text{DT}}(t_0)$ represents the non-dimensional transported molecules to the target over non-dimensional time.
of t_0. Taking Laplace transformation
\[ \mathcal{L}[f](s) = \int_0^\infty f(t)e^{-st}dt, \]
of the non-dimensional number of transported particles yields
\[ \mathcal{L}[\nu_{DT}](s) = \frac{1}{s}\mathcal{L}[J_{DT,0}](s), \] (II.28)
where
\[ \mathcal{L}[J_{DT,0}](s) = \frac{1}{s\cosh(\sqrt{s})}, \] (II.29)
which does not depend on any model parameters. This also gives the asymptotic flux
\[ J_{DT,0}^{ss} = \lim_{t_0 \to \infty} J_{DT,0}(t_0) \]
\[ = \lim_{s \to 0} s\mathcal{L}[J_0](s) = 1. \] (II.30)
One can numerically evaluate \( \nu_{DT}(t) \) by taking the numerical inverse transformation on \( \mathcal{L}[\nu_{DT}](s) \) [25], as shown in Fig. 6(b). Since \( \nu_{DT}(t_0) \) is monotonically increasing, we deduce
\[ \Psi_{DT,0} = \nu_{DT}^{-1}(V_0), \]
which is equivalent to
\[ \Psi_{DT} = \frac{X_{hit}^2}{D} \nu_{DT}^{-1} \left( \frac{DV}{\kappa X_{hit}^2} \right). \] (II.31)
Therefore, the mean transport time is also can be written by
\[ \psi_{DT}(V) = E \left[ \frac{X_{hit}^2}{D} \nu_{DT}^{-1} \left( \frac{DV}{\kappa X_{hit}^2} \right) \right]. \] (II.32)
When the number of particles \( V \) required to transport is large, we can approximate the mean particle transport time by using the fact that the flux converges to a constant. We write the implicit equation as
\[ \int_0^{\Psi_{DT,0}} J_{DT,0}(t_0) - J_{DT,0}^{ss}dt_0 + J_{DT,0}^{ss}\Psi_{DT,0} = V_0, \] (II.33)
which can be approximated by
\[ \int_0^\infty J_{DT,0}(t_0) - J_{DT,0}^{ss}dt_0 + J_{DT,0}^{ss}\Psi_{DT,0} = V_0. \] (II.34)
Substituting into Eq. (II.34) gives
\[ \Psi_{DT,0} = V_0 + \frac{1}{2}. \] (II.35)
which follows that
\[ \Psi_{DT} = \frac{V}{\kappa} + \frac{X_{hit}^2}{2D}. \] (II.36)
Therefore, the asymptotic approximation of the mean particle transport time along protrusion is
\[ \Psi_{DT}(V) = \frac{V}{\kappa} + \frac{1}{2} \frac{X_{hit}^2}{D}. \] (II.37)
Moreover, the integral term in Eq. (II.33) is non-positive, and so we have a lower bound
\[ \Psi_{DT} \geq \frac{V}{\kappa}. \] (II.38)
Numerical comparison in Fig. 6(b) confirms that this is an approximation for large number of molecules \( V \).

### III. DIFFUSIVE PARTICLE TRANSPORT UNDER DEGRADATION

We next consider the classical intercellular signaling mechanism of diffusion with degradation, which is referred to as “impatient” diffusion [26, 27]. The “impatient” molecules eventually either hit the target or are degraded; and we denote the portion of hitting target by \( \rho_{\text{diff}} \). Together with the hitting probability, we again would like to determine the transport time \( \psi_{\text{diff}} \) for delivering the required number of signaling molecules \( V \), in terms of the model parameters. Furthermore, as we did in previous section, we will approximate the transport time in the regime of large \( V \).

We consider a source where signaling particles are released at a constant rate, which then diffuse in two dimensions to find target \( \Omega \subset \mathbb{R}^2 \). To make a “fair” comparison, we assume that the molecule production rate \( \kappa \) and the diffusivity \( D \) are the same as the diffusion along the (1D) protrusion in the direct transport model. We also assume that molecules survive for an exponential amount of time with rate \( g \). Let \( u(x,t) \) be the molecule concentration at position \( x \) and time \( t \). This concentration satisfies
\[ \frac{\partial u}{\partial t} = DV^2u - gu + \kappa \delta(x - x_s), \] (III.1)
where \( x_s \) is the location of the source (and \( \delta \) denotes the delta function in this section, not the difference of a function between the domain). This equation is supplemented by the absorbing boundary condition
\[ u(x \in \partial \Omega, t) = 0, \] (III.2)
where \( \partial \Omega \) is the boundary of \( \Omega \). If \( \mathbb{R}^2 \setminus \Omega \) is unbounded, it requires an asymptotic boundary condition
\[ \lim_{||x|| \to 0} u(x,t) = 0. \] (III.3)
Then the flux to the target satisfies
\[ J_{\text{diff}}(t) = -D \int_{\partial \Omega} \frac{\partial u(x,t)}{\partial n} da, \]
where \( \partial / \partial n \) represents the inward normal derivative to target \( \Omega \). Since the flux converges to the steady-state, the hitting probability should satisfy
\[ J_{\text{diff}}^{\text{ss}} = \kappa \rho_{\text{diff}}. \]

Similar to the diffusion along a protrusion, we can also define the transport time for delivering a required number of molecules \( V \) by
\[ \int_0^{\psi_{\text{diff}}} J_{\text{diff}}(t') dt' = V. \tag{III.4} \]

We determine the transport time by performing Laplace transformation. We first non-dimensionlize using the variables \( x_0 = x/d \), \( t_0 = tD/d^2 \), \( V_0 = VD/(\kappa d^2) \), \( J_{\text{diff},0} = J_{\text{diff}}/\kappa \). The only difference from the previous section is that the length is non-dimensionalized by the minimum distance \( d \) between the source and the target. Then the implicit equation for \( \psi_{\text{diff}} \) becomes
\[ V_{\text{diff}}(\psi_{\text{diff},0}) := \int_0^{\psi_{\text{diff},0}} J_{\text{diff},0}(t'_0) dt'_0 = V_0, \tag{III.5} \]
where \( V_{\text{diff}}(t_0) \) is again the non-dimensional number of transported particles to the target via diffusion over non-dimensional time \( t_0 \). Another Laplace transformation yields
\[ \mathcal{L}[V_{\text{diff}}](s) = \frac{1}{s} \mathcal{L}[J_{\text{diff},0}](s), \tag{III.6} \]
which depends on the non-dimensional target radius \( r_0 = r/d \) and degradation rate \( g_0 = gd^2/D \). This allows to find the asymptotic flux
\[ J_{\text{diff},0}^{\text{ss}} = \lim_{s \to \infty} s \mathcal{L}[J_{\text{diff},0}](s) \]
\[ = \rho_{\text{diff}}, \]
which is the same as the hitting probability of a single diffusive particle. Another numerical inversion of Laplace transformation gives \( V_{\text{diff}}(t) \). Then the particle transport time takes the form
\[ \psi_{\text{diff}}(V) = s^2 D V^{-1}_{\text{diff}} \left( \frac{DV}{\kappa d^2} \right). \tag{III.7} \]

We approximate the particle transport time for large number of molecules \( V \) by
\[ \int_0^\infty J_{\text{diff},0}(t'_0) - J_{\text{diff},0}^{\text{ss}} dt'_0 + J_{\text{diff},0}^{\text{ss}} \psi_{\text{diff},0} = V_0, \]
which follows that
\[ \psi_{\text{diff},0}(V_0) = \frac{V_0}{\rho_{\text{diff}}} + \frac{1}{2} \psi_{\text{diff}}, \tag{III.8} \]

Therefore, we have
\[ \psi_{\text{diff}} = 2 \int_0^\infty 1 - \frac{J_{\text{diff},0}(t'_0)}{J_{\text{diff},0}^{\text{ss}}} dt'_0. \]

The exact formulation and detailed derivation can be found in Appendix B. Numerical simulation in Fig. 7 shows that the approximation agrees with the direct inversion for a large number of molecules.

### IV. UTILITY ANALYSIS

How do we quantify the “efficiency” of an intercellular signaling transport mechanism? One important consideration is the energy cost for transporting signaling molecules from a source cell to a target cell. The cost arises from synthesizing signaling molecules and polymerizing filaments for cellular protrusions. If we consider only the energy aspect, it would give an absurd prediction for optimal parameters. For example, the energy cost for contact formation, which is proportional to the TEPL in (II.15), is minimized when the projection rate is zero – even though, in reality, cells extend multiple protrusions to find the target [3, 4]. Another important consideration is the benefit accrued by a cell if it makes a signal quickly. Thus, another crucial aspect of efficiency is the time required for transporting a required amount of signaling particles.

Under competition between energy cost and total transport time, one natural measure of the signaling efficiency is their ratio
\[ \gamma = E \left[ \frac{E}{\gamma_0 T} \right], \]

![FIG. 7. Molecule transport time of the diffusion model \( \psi_{\text{diff}} \) to the target as a function of non-dimensional particle number \( V_0 \) in case of the disk shape (left panel) and the annulus shape (right panel) with various non-dimensional radius \( r_0 \). Exact transport time (solid curve) is compared with the asymptotic approximation (dotted curve). Non-dimensional degradation rate is chosen by \( d_0 = 1/2 \).](image)
where $\gamma_0$ is a conversion factor from transport time to benefit. In this formulation we assume the benefit accrued by more rapid signaling is linear in the rate of signaling transmission, although in some biological situations benefits of rapid signaling may be non-linear. The resulting cost-benefit ratio is then

$$
\gamma = \gamma_0^{-1}E[\mathcal{E}]T, \quad \text{(IV.1)}
$$

Aside from this cost-benefit ratio, we might alternatively consider a utility function given by the total energetic cost of a successful signal

$$
\eta = E[\mathcal{E}] + \eta_0 E[T], \quad \text{(IV.2)}
$$

where the second term penalizes a long signaling process due to the energetic cost of maintaining cell homeostasis during the signaling search process (the factor $\eta_0$ denotes a conversion between time and energetic cost of homeostasis). In this section, we determine and compare the cost-benefit ratio of the transport mechanisms. In particular, we show that the direct transport is optimized at some protrusion projection rate. Then we extend the qualitative results for the cost-benefit ratio to measure of efficiency based on total energetic cost.

### A. Efficient contact formation at optimal projection rate

First, we consider the contact formation process of the direct transport model, temporarily neglecting molecule transport following contact formation. Let $\Delta_{DT}$ denote by the energy cost of protrusion polymerization per unit length. Then the total energy cost for contact formation is proportional to the TEPL

$$
\mathcal{E}_{DT} = \Delta_{DT} L_{DT},
$$

assuming that the energy is not required for depolymerization. Together with the contact formation time $T_{DT}$, the cost-benefit ratio of direct contact formation is then

$$
\gamma_{DT} = \frac{E[\mathcal{E}_{DT}]T_{DT}}{\gamma_0^{-1}E[L_{DT}T_{DT}]},
$$

where $\gamma_{DT} = \gamma_0^{-1} \Delta_{DT}$.

The correlation of $L_{DT}$ and $T_{DT}$ can be analyzed under the rare-event approximation

$$
\tilde{\gamma}_{DT} = \gamma_0^{-1}E[L_{DT}T_{DT}], \quad \text{(IV.3)}
$$

Since $K_0$ and $X_{hit,K_0}$ are independent, one can condition the expectation value by setting $K_0 = j$ and $X_{hit,K_0} = x$

$$
\frac{\tilde{\gamma}_{DT,j}(x)}{\gamma_0^{-1}} = \mathbb{E}[L_{DT}T_{DT}|K_0 = j, X_{hit,K_0} = x] = \frac{j\lambda_{DT,j}}{\kappa_{DT}} + \frac{(j-1)x}{v_+} + \frac{x^2}{v_+} + \frac{x}{v_+} \mathbb{E}\left[\sum_{k=1}^{N_0(x/v_+)} X_k\right]. \quad \text{(IV.4)}
$$

Using Eq. (II.13) yields that the last term takes the form of

$$
\mathbb{E}\left[\sum_{k=1}^{N_0(x/v_+)} X_k\right] = \frac{\kappa_{DT} x \lambda_0}{v_+}, \quad \text{(IV.5)}
$$

which follows that

$$
\frac{\tilde{\gamma}_{DT,j}(x)}{\gamma_0^{-1}} = \frac{j\lambda_{DT,j}}{\kappa_{DT}} + \frac{(j-1)x \lambda_{miss}}{v_+} + \left(\frac{1}{v_+} + \frac{\kappa_{DT} \lambda_0}{v_+^2}\right)x^2. \quad \text{(IV.6)}
$$

Taking expectation with respect to $x = X_{hit}$

$$
\frac{\tilde{\gamma}_{DT,j}}{\gamma_0^{-1}} = \mathbb{E}\left[\frac{\tilde{\gamma}_{DT,j}(X_{hit})}{\gamma_0^{-1}}\right] = \frac{j\lambda_{DT,j}}{\kappa_{DT}} + (j-1) \lambda_{hit} \lambda_{miss} + \left(\frac{1}{v_+} + \frac{\kappa_{DT} \lambda_0}{v_+^2}\right) \mathbb{E}\left[X_{hit}^2\right]. \quad \text{(IV.7)}
$$

Another application of the total expectation theorem gives the rare-event approximation of the cost-benefit ra-

![Graph showing cost-benefit ratio of contact formation by protrusions with various parameters.](image)

FIG. 8. Cost-benefit ratio of contact formation by protrusions with various parameters in case of the disk-shaped target (solid curve) and the annulus-shaped target (dotted curve). There exist an optimal projection rate and mean protrusion length (yellow circle). Parameters are chosen as follows: $d = 10 \mu m$ and the others are the same as Fig. 5.
The optimal projection rate monotonically decreases as the coefficient $\chi$ becomes balanced at the optimal rate of protrusion. Thus, the time to the target. These two time intervals are the projection time and the travel time to the target cell (Eq. (IV.10)). Parameters are the same as Fig. 8.

FIG. 9. Optimal protrusion rate $\kappa_{\text{DT}}$ with various parameters, together with the statistics of the single protrusion event $\rho_{\text{DT}}$ and $\tau_{\text{hit}}$. The optimal projection rate satisfies Eq. (IV.10). Parameters are the same as Fig. 8.

is nearly constant if the protrusions are always projected towards the target. However, the optimal projection rate has a non-monotonic behavior with respect to the target distance $d$. For a target that is farther from the source, the source cell prefers a faster projection rate because the target cell is harder to reach. The optimal projection rate is also fast when the target is close, even though the hitting probability is high, because the optimal rate balances the projection time for a hitting event and the travel time to the target cell (Eq. IV.10). When the target is closer, the traveling time is shorter, which requires a shorter projection time for the hitting event by a faster projection rate.

B. Optimal projection rate with particle transport

Now we reconsider the cost-benefit ratio, including the process of particle transport along the protrusion following contact with a target. In addition to the contact formation time, it now takes more time to transport the required number of particles $V$ along the protrusion

$$T_{\Sigma,\text{DT}} = T_{\text{DT}} + \Psi_{\text{DT}}(V; X_{\text{hit}}).$$

Since there is no loss of particles by the protrusion-mediated transport, the total energy cost is

$$E_{\Sigma,\text{DT}} = E_{\text{DT}} + \Delta_p V,$$

where $\Delta_p$ is the energy price for synthesizing a single signaling particle. Therefore, the mean cost-benefit ratio becomes

$$\gamma_{\Sigma,\text{DT}} = \gamma_0^{-1}E[E_{\Sigma,\text{DT}}T_{\Sigma,\text{DT}}].$$
Similar to the previous section, we have the rare-event approximation of the cost-benefit ratio
\[
\frac{\gamma_{\Sigma, DT}}{\gamma_{0,DT}}^\epsilon = \mathbb{E}\left[\left(\tilde{T}_{DT} + \Psi_{DT}(V; X_{hit})\right) \times \left(\Delta_{DT}\tilde{L}_{DT} + \Delta_p V\right)\right] = \gamma_{DT} + \Delta_p V \left(\tilde{T}_{DT} + \psi^{(0)}(V)\right) + \Delta_{DT}\mathbb{E}[\tilde{L}_{DT}\Psi_{DT}(V; X_{hit})],
\]
where \(\psi^{(k)}(V) = \mathbb{E}[X_{hit}^k\Psi_{DT}(V; X_{hit})]\) for \(k = 0, 1, \ldots\). Since \(\tilde{L}_{DT}\) also contains \(X_{hit}\), the last term is deduced to with the higher order moment term
\[
\mathbb{E}[\tilde{L}_{DT}\Psi_{DT}(V; X_{hit})] = 1 - \frac{\rho_{DT}}{\rho_{DT}}\lambda_{\text{miss}}\psi^{(0)}(V) + \frac{1}{v_{\tau}}(\nu_{+} + \kappa_{DT}\lambda_0)\psi^{(1)}_{DT}(V).\]

This approximation can be written as a power series of \(\kappa_{DT}\)
\[
\frac{\gamma_{\Sigma, DT}}{\gamma_{0,DT}}^\epsilon = \frac{1}{\kappa_{DT}} \left(\frac{\lambda_0 Q^2}{\rho_{DT}} + \frac{\Delta_{q} V}{\Delta_{DT}\rho_{DT}}\right) + \mathcal{R}_{\Sigma, DT}(V) + \kappa_{DT}\lambda_0 \left(\mathbb{E}[T_{hit}^2] + \frac{\psi^{(1)}_{DT}(V)}{v_{\tau}}\right),
\]
where \(\mathcal{R}_{\Sigma, DT}(V) = \mathcal{R}_{DT} + (1 - \rho_{DT})\lambda_{\text{miss}}\psi^{(0)}_{DT}(V)/\rho_{DT} + \Delta_{q} V\psi^{(0)}_{DT}(V)/\Delta_{DT} + \psi^{(1)}_{DT}(V)\). In contrast to Eq. (IV.9), there are now additional terms on the coefficients, which arise from the particle transport, including the energy cost for molecule production \((\Delta_{q} V)\) and the particle transport time along the protrusion \((\psi^{(1)}_{DT}(V))\).

Again, one can find the optimal projection rate by solving the critical condition \(0 = \partial \gamma_{\Sigma, DT}/\partial \kappa_{DT}\), which follows that
\[
\left(\frac{\kappa_{\Sigma, DT}^*}{\kappa_{DT}^*}\right)^2 = \frac{1}{1 + \frac{\Delta_{q} V}{\Delta_{DT}\rho_{DT}\lambda_0 Q^2}} \left(\frac{\psi^{(1)}_{DT}(V)}{v_{\tau}}\right) \mathbb{E}[T_{hit}^2].
\]

This yields the following equivalent condition
\[
\kappa_{\Sigma, DT}^* > \kappa_{DT}^* \iff \frac{\varepsilon_p}{\varepsilon_{DT}} > \chi_\epsilon(V),\]
where the energy rates satisfy
\[
\varepsilon_p = \kappa_{\Sigma, DT}^* \Delta_p, \quad \varepsilon_{DT} = \Delta_{DT}\lambda_0 \kappa_{DT}^*,
\]
and the critical energy ratio is
\[
\chi_\epsilon(V) = \frac{\lambda_0\kappa_{\Sigma, DT}^* \psi^{(1)}_{DT}(V)}{\lambda_{hit} V}.
\]

Eq. (IV.16) is that, for given \(V\), if the particle synthesis energy rate is sufficiently expensive than the average contact formation energy rate, cells prefers the faster projection rate to be optimized. Otherwise, the smaller protrusion rate is more efficient.

We are also interested in the cost-benefit ratio, and optimal projection rate, in the limit of a large number of transporting particles, \(V\). Using the fact that
\[
V \frac{\gamma_{DT}(V)}{\gamma_{DT}(V)} \leq \Psi_{DT}(V; X_{hit}) \leq V \frac{\gamma_{hit}^2}{2D},
\]
we have the limit
\[
\lim_{V \rightarrow \infty} \chi_\epsilon(V) = \chi_0.
\]

Therefore, the asymptotic critical condition is
\[
\kappa_{\Sigma, DT}^* > \kappa_{DT}^* \iff \frac{\varepsilon_p}{\varepsilon_{DT}} > \chi_0,\]
in the limit of a large number of transporting particles. In particular, we can extend the asymptotic condition to any number of particles
\[
\frac{\varepsilon_p}{\varepsilon_{DT}} < \chi_0 \implies \kappa_{\Sigma, DT}^* < \kappa_{DT}^*,
\]
in accordance with the following inequality derived from Eq. (II.39)
\[
\chi_\epsilon(V) \geq \chi_0.
\]

for any \(V\). In other words, the optimal projection rate with particle transport is always slower than the optimal rate without particle transport, if the molecule synthesis cost is sufficiently cheap compared to protrusion elongation cost, regardless of \(V\).

However, this strict ordering of optimal project rates with or without particle transport in Eq. (IV.19) does not hold but depends on \(V\) when the energy for producing signaling molecules is sufficiently large compared to the energy for contact formation, as shown in Fig. 10. In other words, there exists a number \(V_{DT,c}\) such that
\[
\frac{\varepsilon_p}{\varepsilon_{DT}} > \chi_0 \implies \left\{\begin{array}{l}
\kappa_{\Sigma, DT}^* < \kappa_{DT}^*, \quad V < V_{DT,c}^* \\kappa_{\Sigma, DT}^* > \kappa_{DT}^*, \quad V > V_{DT,c}^*.
\end{array}\right.
\]

This statement can be shown by using a standard regular perturbation argument. Expanding \(\Psi_{DT}(V) = \Psi_{DT,0}V^\beta + \cdots\) and substituting into Eq. (II.26), we determine the leading order \(\beta = 1/2\). This follows that
\[
\chi_\epsilon(V) \sim V^{-1/2},
\]
for small \(V\). Therefore, for any energy cost ratio \(\varepsilon_p/\varepsilon_{DT}\), there exists small \(V_{DT,c} > 0\) such that \(\chi_\epsilon(V) > \varepsilon_p/\varepsilon_{DT}\) for all \(V < V_{DT,c}\).

One interesting observation is that the ratio of optimal projection rates with or without particle transport is non-monotonic in \(V\), as shown in Fig. 10. This arises from
the effective transport behavior of diffusion along a 1D domain. At large $V$, the fluxes at both ends of protrusion converge to the maximum, and the transport behaves like an advective process. Thus, in order to minimize the cost-benefit ratio, the optimal rate of protrusion is faster when accounting for the transport process, because the protrusion elongation cost is relatively cheap. However, at small $V$, particles are transported more like diffusion, with longer traveling time. This particle transport time dominates the cost-benefit ratio so that the protrusion elongation cost becomes relatively large, and the optimal rate of protrusion is slower when accounting for particle transport.

C. Signaling by direct transport versus diffusion

We can form expectations for when a cell would evolve to use direct transport or, alternatively, impatient diffusion for signaling, by inspecting the cost-benefit ratio in each case. To do this we now analyze the cost-benefit ratio under impatient diffusion. Due to the degradation of signaling molecules, the direct transport mechanism is cheaper than the diffusion mechanism, because the contact formation energy cost per transported particle is cheaper than the diffusion mechanism, because the contact formation energy cost per transported particle is cheaper than the diffusion mechanism. As a result, the critical number of particles above which direct transport is preferable, namely:

$$\gamma_{\Sigma,D,T}(V_{\Sigma,c}) = \gamma_{\Sigma,diff}(V_{\Sigma,c}).$$

For simplicity, we use the rare-event approximation to study the critical number $V_{\Sigma,c}$ by solving

$$\gamma_{\Sigma}(V) := \gamma_{\Sigma,diff}(V) - \gamma_{\Sigma,D,T}(V) = 0.$$  

Numerical simulation in Fig. 11(a) confirms the existence of the critical number of particles $V_{\Sigma,c}$ that determines whether diffusion or direct transport is preferable, namely:

The cost-benefit ratio under the diffusion mechanism takes the form of

$$\frac{\gamma_{\Sigma,diff}}{\gamma_0} = \frac{\mathcal{E}_{\Sigma,diff}}{\gamma_0} \sim \frac{\Delta_p V^2}{\kappa \rho_{diff}}.$$  

Finally, we can compare the cost-benefit ratio of two signaling mechanisms. We first investigate the asymptotic behavior of the diffusion-based cost-benefit ratio at large and small number of transporting particles, $V$. At large $V$, Eqs. (IV.14) and (IV.22) indicate that the leading order behavior of the ratios are

$$\frac{\gamma_{\Sigma,D,T}}{\gamma_0} \sim \frac{\Delta_p V^2}{\kappa}, \quad \frac{\gamma_{\Sigma,diff}}{\gamma_0} \sim \frac{\Delta_p V^2}{\kappa \rho_{diff}}.$$  

Since $\rho_{diff} < 1$, then $\gamma_{\Sigma,D,T} < \gamma_{\Sigma,diff}$ for sufficiently large $V$. That is, if the cell must deliver large size of signaling molecules, the direct transport mechanism is cheaper than the diffusion mechanism, because the contact formation energy cost per transported particle is cheaper. On the other hand, as $V \to 0$, the cost-benefit ratios converge to

$$\lim_{V \to 0} \gamma_{\Sigma,D,T}(V) = \gamma_{D,T}, \quad \lim_{V \to 0} \gamma_{\Sigma,diff}(V) = 0.$$  

This follows that $\gamma_{\Sigma,D,T} > \gamma_{\Sigma,diff}$ for sufficiently small $V$. In this limit, due to the cost of contact formation, the diffusion mechanism is always cheaper than the direct transport. This guarantees the existence of the critical number of particles $V_{\Sigma,c}$ that determines whether diffusion or direct transport is preferable, namely:

$$\gamma_{\Sigma,D,T}(V_{\Sigma,c}) = \gamma_{\Sigma,diff}(V_{\Sigma,c}).$$

And so the cost-benefit ratio under the diffusion mechanism takes the form of

$$\frac{\gamma_{\Sigma,diff}}{\gamma_0} = \frac{\mathcal{E}_{\Sigma,diff} \mathcal{T}_{\Sigma,diff}}{\gamma_0} \sim \frac{\Delta_p V^2}{\rho_{diff}}.$$  

where

$$\gamma_{\Sigma}(V) = \gamma_{\Sigma,diff}(V_{\Sigma,c}) - \gamma_{\Sigma,D,T}(V_{\Sigma,c}),$$

and

$$\gamma_{\Sigma,D,T}(V_{\Sigma,c}) - \gamma_{\Sigma,diff}(V_{\Sigma,c}) = \gamma_{\Sigma,D,T}(V_{\Sigma,c}) - \gamma_{\Sigma,diff}(V_{\Sigma,c}).$$

Therefore, the critical number of transport particles is bounded by

$$V_{\Sigma,c} \leq \bar{V}_{\Sigma,c} \leq \bar{V}_{\Sigma}.$$
where \( \Sigma_\gamma(V) = 0 \) and \( \Sigma_\psi(V) = 0 \).

Numerical simulation in Fig. 11(b) shows the behavior of the critical transport size as a function of various parameters by plotting the upper and lower bounds. If the target is far from the source cell, then the direct transport mechanism is generally preferred, unless the required number of transport molecules is very small (that is, \( \bar{V}_{\Sigma,c} \) is small), because the the protrusion search process is cheaper than diffusive particle synthesis. If the projections are aimed at the target more precisely, then again the direct contact model is typically preferred \( (\bar{V}_{\Sigma,c} \) small) because contact formation cost is small. In the case of annular target, the critical number is independent of \( \sigma \) because the target distance is uniform for any projection angle. At small degradation rates, the hitting probability of diffusive particles is higher and so diffusion is typically preferred \( (\bar{V}_{\Sigma,c} \) large), especially so for disk-shaped target because it has a smaller hitting probability. And for large elongation cost, the diffusion model is typically preferred \( (\bar{V}_{\Sigma,c} \) large, especially for a disk-shaped target).

One natural question whether, for any set of parameters, direct transport can always dominate diffusion, regardless of the size of required transport molecules, \( V \). More precisely, we would like to find a bounded set of parameters such that

\[
\gamma_\Sigma(V) \geq 0,
\]

for all \( V \). Here we introduce the rare-event approximation for analytic simplicity. We choose \( \alpha_1 = \Delta_{DT} \) and \( \alpha_2 = \psi_{\text{diff}} \) as the parameters for the dominant condition, then the cost-benefit ratio takes the form of

\[
\gamma_\Sigma(\alpha_1, \alpha_2, V) = \varphi_0(V) - \alpha_1 \varphi_1(V) - \varphi_2(\alpha_2; V), \quad (\text{IV.30})
\]

where

\[
\varphi_0(V) = \Delta_\rho V \left( \frac{\psi_{\text{diff}}(V)}{\rho_{\text{diff}}} - \psi_{\text{DT}}^{(0)}(V) \right),
\]

\[
\varphi_1(V) = R_{\Sigma, \text{DT}}(V) - R_{\text{DT}}, \quad \text{and} \quad \varphi_2(\alpha; V)/2 = \alpha \text{Var}[X_{\text{hit}}^{\Sigma}] \hat{\lambda}_0/\rho_{\text{DT}} + \rho_{\text{DT}}^2 (\lambda_0 Q^2 + \Delta_\rho \rho_{\text{DT}} V/\Delta_{\text{DT}}) \times (\alpha^2 \text{Var}[X_{\text{hit}}^{\Sigma}] + \alpha \psi_{\text{DT}}^{(1)}(V))^{1/2}. \quad \text{(IV.30)}
\]

We want to find non-zero \( \alpha_1, \alpha_2 \) such that there is a lower bound \( \gamma_\Sigma(V) \geq \gamma_{\Sigma,0} > 0 \) for all \( V \). If \( \varphi_0(V) \leq 0 \) for some interval including \( V = 0 \), then \( \gamma_\Sigma(V) < 0 \) over the interval. Thus, one cannot find any non-zero parameters. In other words, the diffusion mechanism dominates the direct transport mechanism over the interval. Although \( \varphi_0(V) \geq 0 \) for all \( V \), we still cannot find the set of parameters because

\[
\lim_{V \to 0} \gamma_\Sigma(\alpha_1, \alpha_2, V) = \varphi_2(\alpha_2, 0) < 0, \quad (\text{IV.31})
\]

for non-zero \( \alpha_2 \). This result implies that for finite \( \alpha_1 \) and \( \alpha_2 \), it is impossible that the direct transport always dominates the diffusion mechanism, regardless of \( V \), for finite protrusion growth speed and the elongation cost.
D. Total energetic cost

As an alternative to the cost-benefit ratio measure of signaling efficiency, we can also study the that the total energetic cost (IV.2) of direct transport and impatient diffusion. In general, the total energetic cost has qualitatively similar behavior to the cost-benefit ratio, such as an optimal projection rate and the critical number discussed in previous section. We show that most of qualitative properties of the cost-benefit ratio also hold for total energetic cost.

There exists and optimal projection rate of the total energetic cost. The total energetic cost of the contact formation can be written by

\[ \eta_{\text{DT}} = \Delta_{\text{DT}} E[\mathcal{L}_{\text{DT}}] + \eta_0 E[\mathcal{T}_{\text{DT}}], \] (IV.32)

whose rare-event approximation is

\[ \tilde{\eta}_{\text{DT}} = \Delta_{\text{DT}} \lambda_0 \theta_{\text{hit}} \kappa_{\text{DT}} + \frac{\eta_0}{\kappa_{\text{DT}} \rho_{\text{DT}}} + \tilde{\eta}_{\text{DT},0}, \] (IV.33)

Substituting (II.8) and (II.15) into the equation yields

\[ \tilde{\eta}_{\text{DT}} = \Delta_{\text{DT}} \lambda_0 \theta_{\text{hit}} \kappa_{\text{DT}} + \frac{\eta_0}{\kappa_{\text{DT}} \rho_{\text{DT}}} + \tilde{\eta}_{\text{DT},0}, \] (IV.34)

where \( \tilde{\eta}_{\text{DT},0} = \Delta_{\text{DT}} \lambda_0 / \rho_{\text{DT}} + \eta_0 \theta_{\text{hit}}. \) This is minimized at

\[ (\kappa_{\text{DT}}^{-1} \rho_{\text{DT}}^{-1})^2 = \frac{\Delta_{\text{DT}} \lambda_0}{\eta_0 \rho_{\text{DT}}} \theta_{\text{hit}}, \] (IV.35)

where the fraction in the right-hand side represents the energetic cost of maintaining metabolism during contact formation. That is, this optimal condition balances the time to generate a protrusion that will hit the target \((\kappa_{\text{DT}}^{-1} \rho_{\text{DT}}^{-1})\) and the geometric mean of the traveling time (converted into energetic cost) for the protrusion to hit the target \((\theta_{\text{hit}})\), which is analogous to Eq. (IV.10).

Fig. 12 also shows the existence of the optimal projection and similar qualitative behavior seen in Fig. 8.

We next consider the total energetic cost of direct transport model with particle transport. Setting \( \mathcal{E} = \mathcal{E}_{\Sigma,\text{DT}} \) and \( \mathcal{T} = \mathcal{T}_{\Sigma,\text{DT}} \) gives

\[ \eta_{\Sigma,\text{DT}} = \eta_{\text{DT}} + \Delta_p V + \eta_0 \psi_{\text{DT}}^{(0)}(V). \] (IV.36)

Since the second and the third terms are independent of the projection rate \( \kappa_{\text{DT}} \), the optimal condition with particle transport is the same as without particle transport

\[ 0 = \frac{\partial \eta_{\Sigma,\text{DT}}}{\partial \kappa_{\text{DT}}} = \frac{\partial \eta_{\text{DT}}}{\partial \kappa_{\text{DT}}}, \] (IV.37)

This implies that the optimal projection rate of the total energetic cost is independent to the number of transporting particles, which is a qualitatively different behavior than the cost-benefit ratio in Eq. (IV.20).

The total energetic cost shows the same asymptotic behavior as the cost-benefit ratio with respect to the number of transporting particles. Similar to Eq. (IV.36), one can define the total energetic cost of the diffusion mechanism

\[ \eta_{\Sigma,\text{diff}} = \frac{\Delta_p V}{\rho_{\text{diff}}} + \eta_0 \psi_{\text{diff}}(V). \] (IV.38)

As \( V \to 0 \), diffusion is more efficient than direct contact

\[ \lim_{V \to 0} \eta_{\Sigma,\text{DT}} = \eta_{\text{DT}}, \quad \lim_{V \to 0} \eta_{\Sigma,\text{diff}} = 0, \] (IV.39)

and the opposite holds as \( V \to \infty \) because

\[ \frac{\eta_{\Sigma,\text{DT}}}{V} \sim \Delta_p + \frac{\eta_0}{\kappa}, \quad \frac{\eta_{\Sigma,\text{diff}}}{V} \sim \frac{1}{\rho_{\text{diff}}} \left( \Delta_p + \frac{\eta_0}{\kappa} \right), \] (IV.40)

and \( \rho_{\text{diff}} < 1 \). Therefore, there is a critical number satisfying \( \eta_{\Sigma,\text{DT}}(V) = \eta_{\Sigma,\text{diff}}(V) \), which is analogous to Eq. (IV.39) and (IV.40), that determines whether diffusion or direct transport is more efficient. Fig. 13 depicts the critical number for the total energetic function, as a function of various parameters. The behavior is qualitatively similar to that of the cost-benefit ratio analysis.

V. DISCUSSION

In this paper, we have compared two qualitatively different mechanisms of intercellular signaling: direct transport (DT) and impatient diffusion. We first developed a protrusion-based model of direct transport, in which a
source cell projects a series of protrusions in two dimensions until making contact with the target cell. Once contact is established, signaling molecules are then transported via diffusion along the one-dimensional protrusion. We calculated the mean effective protrusion length of a single protrusion, conditioned on either hitting or missing the target; and then used this to develop a rare-event approximation for the mean first passage time and mean total effective protrusion length in the case of multiple protrusions. Finally, we calculated the transport time for a required number of diffusive particles along an established protrusion. By contrast, in the case of diffusive signaling, we calculated the hitting probability and the transport time of diffusive molecules with degradation in two dimensions. We then introduced the cost-benefit ratio as a measure of efficiency of these two mechanisms, comparing their relative efficiency across a range of parameters. We also compared the mechanisms with respect to a different measure of efficiency, the total energetic cost, which shows qualitatively similar behavior with to the cost-benefit ratio.

Two specific conditions that optimize and favor direct transport emerge from our analysis. First, cellular protrusions that are accurately directed towards the target cell ($\sigma \ll \pi$) and whose length is similar to the target distance ($\lambda L \approx d$) minimize the cost-benefit ratio (as shown in Fig. 8). Indeed, theoretical analysis suggests that cells can gather accurate information about the location of a target cell by optimizing the distribution of receptors on the cell surface [28]. Therefore, in the case of bidirectional communications, we hypothesize that DT mechanism may be efficiently utilized for responder cells. Empirical examples of this phenomenon are known to occur, as cells generate additional cytonemes by feedback signals following contact formation during FGF morphogen gradient formation in Drosophila [29]. Second, the projection rate that optimizes contact formation, neglecting particle transport, balances the time required to initiate a successful protrusion with the time required for that protrusion to actually hit the target cell (Eq. IV.10). Furthermore, the difference between the optimal projection rate with and without particle transport depends on the energy cost of contact formation versus particle synthesis ($\epsilon_p/\epsilon_{DT}$), for a given number of transport particles (as shown in Eq. (IV.19) and (IV.20)).

Our comparison of direct transport versus impatient diffusion highlights a critical number of required signaling molecules, $V_{\Sigma,c}$, that determines which of the two mechanisms is more efficient, for any given set of model parameters. In other words, the more efficient mechanism will depend on the total number of required transport particles $V$, even when all other conditions are the same. In particular, the direct model tends to be preferred when the target cell is far from the source cell, across a very broad range of required transport molecules (as seen in Fig. 11 and 13). This result helps to explain why cytonemes and other signaling protrusions are often observed in long-range intercellular signaling [30, 31]. But when the source and target cells are in close proximity, by contrast, direct transport is more efficient only when the required number of transport molecules is very large. Indeed, short signaling protrusions are observed during cell differentiation [32], and this can be understood as the result of the high number of required transport particles in the context of long-term signaling between niche cells and germ cells.

Although a quantitative comparison between signaling via direct transport versus diffusion requires a specific choice of efficiency measure, most of our qualitative conclusions hold for both of the measures we have studied: a cost benefit-to-cost ratio of signaling speed to metabolic energy cost, as well as a metric based purely on energetic costs. Both utility functions predict an optimal projection rate and a critical number of required signaling molecules. Moreover, the critical number of signaling molecules has a similar dependence on variation in other model parameters, such as the distance to target, information about target location, degradation rate of
signaling molecules, and synthesis and elongation costs.

Our analysis has several limitations. We have assumed that signaling molecules degrade under the impatient two-dimensional diffusion model, whereas we assume they are protected against degradation when diffusing along the interior of a cellular protrusion. This assumption, which may be realistic in most settings, nonetheless penalizes the diffusion mechanism compared to direct transport. This affects the asymptotic behavior of the cost-benefit ratio at large $V$, that is, Eq. (IV.23) becomes

$$
\gamma_{\Sigma,DT} \sim \frac{\Delta_p V^2}{\kappa \rho_{diff,1}}, \quad \gamma_{\Sigma,diff} \sim \frac{\Delta_p V^2}{\kappa \rho_{diff,2}}, \quad (V.1)
$$

where $\rho_{diff,k}$ is the hitting probability of signaling molecules in $k$-dimensional space to the target before degradation. For a disk target, one can show that $\rho_{diff,1} > \rho_{diff,2}$ and thus our qualitative results do not change if we allow degradation of particles within the protrusion. However, we have the opposite relation in case of an annular target, which implies that direct transport model can be monotonically less efficient than diffusion while incurring an additional cost for contact formation. We have also assumed that signaling molecules and protrusions are nucleated from a point source. Indeed, the nucleation process can happen on the source cell surface, which can be approximated by introducing multiple point sources on the surface. This geometric effect can qualitatively affect our analytic results, but are expected to give the qualitatively similar result when the overall rate of multiple sources is the same as the rate of the single source.

There are many open questions and avenues for future research based on the simple modeling framework we have developed. One important area concerns the cost-benefit ratio as a measure of signaling efficiency. Our analysis has assumed that benefits are linear in the speed of signaling (that is, the inverse of the time to deliver the required number of signaling molecules). But there may be biological contexts in which benefits are saturating, strictly sub-linear, or even non-concave in the speed of signaling – and this distinction could qualitatively change the performance of direct transport relative impatient diffusion as a mechanism of signaling. A related set of questions pertain to a source cell that communicates with multiple target cells. In this setting, which is common in biological contexts, the benefits of successful signaling may again be sub- or super-additive across targets, depending upon whether reaching multiple targets is strictly required for producing a successful biological function, or merely additionally beneficial. Analysis of mean passage times and measures of efficiency in the setting of multiple targets remains an important and rich area for future research.

**APPENDIX A: SINGLE PROTRUSION EVENT WITH IDEALIZED TARGETS**

In this section, we present the computation for the hitting probability and the conditional MEPLs in two idealized targets.

1. **Disk-shaped target**

In terms of target parameters, the target distance function is

$$
\zeta(\Theta) = (r + d) \cos \Theta - \sqrt{r^2 - (r + d)^2} \sin^2 \Theta, \quad (A.1)
$$

for $\Theta \in \phi(\Omega)$. Then the cumulative density function (cdf) of EPL can be written by

$$
F_Z(x) = \int_{\zeta(y) \leq x} \rho_\Theta(y) dy, \quad (A.2)
$$

which yields

$$
F_Z(x) = \begin{cases} 
0, & x \leq d \\
\frac{1}{\sigma} \left( \min \{ \zeta^{-1}(x), \phi_{max}, \sigma \} \right), & x > d.
\end{cases} \quad (A.3)
$$

Here $\phi_{max} = \max \{ \phi(\Omega) \} = \sin^{-1}(r/(r + d))$. Substituting into Eq. (II.1) and performing integration yields

$$
\rho_{DT} = \frac{1}{\sigma} \int_0^{\sigma_0} e^{-\zeta(y)/\lambda L} dy, \quad (A.4)
$$

where $\sigma_0 = \min \{ \phi_{max}, \sigma \}$. One can also calculate the conditional MEPLs

$$
\lambda_{hit} = \frac{1}{\rho_{DT}} \left[ \frac{1}{\sigma} \int_0^{\sigma_0} \zeta(y) e^{-\zeta(y)/\lambda L} dy \right], \quad (A.5)
$$

and

$$
\lambda_{miss} = \frac{1}{1 - \rho_{DT}} \left[ \lambda_L - \frac{\sigma_0}{\sigma} \left( \frac{\zeta(\sigma_0)}{\lambda L} e^{-\zeta(\sigma_0)/\lambda L} \right) \right. \\
- \left. \frac{1}{\sigma \lambda L} \int_d^{\zeta(\sigma_0)} xe^{-x/\lambda L} \zeta^{-1}(x) dx \right]. \quad (A.6)
$$

2. **Annulus-shaped target**

Similarly, we compute the same quantities for the annulus-shaped target. The major difference is that the target distance is always $d_s$ for any $\Theta$, which yields

$$
F_Z(x) = \mathbb{1}_{[d_s, \infty)}(x). \quad (A.7)
$$
Similar to the previous section, we have
\[
\rho_{\text{DT}} = e^{-d_s/\lambda_L},
\]  
(A.8)
and
\[
\lambda_{\text{hit}} = d_s, \quad \lambda_{\text{miss}} = \lambda_L - \frac{d_s}{e^{d_s/\lambda_L} - 1}. \tag{A.9}
\]

3. Error estimation

We calculate the relative difference of \(\rho_{\text{DT}}^{-1}\) and \(\lambda_{\text{hit}}\) between the disk-shaped domain \(\Omega\) and the “polar rectangle” \(\bar{\Omega}\). It can make a contact to \(\bar{\Omega}\) by a single protrusion if \(\Theta \in [-\sigma_0, \sigma_0]\) and \(L \geq d\), which gives
\[
\rho_{\text{DT}}(\bar{\Omega}) = \frac{\sigma_0}{\sigma} e^{-d/\lambda_L}. \tag{A.10}
\]
Using Eq. (A.4) yields
\[
\frac{\delta [\rho_{\text{DT}}^{-1}]}{\rho_{\text{DT}}} = 1 - \frac{1}{\sigma_0} \int_0^{\sigma_0} e^{-(\zeta(y) - d)/\lambda_L} dy \tag{A.11}
\]
Since
\[
\zeta(y) < r + d, \tag{A.12}
\]
we have
\[
\frac{1}{\sigma_0} \int_0^{\sigma_0} e^{-(\zeta(y) - d)/\lambda_L} dy \geq e^{-r/\lambda_L}.
\]
Substituting this inequality into Eq. (A.11) gives
\[
\frac{\delta [\rho_{\text{DT}}^{-1}]}{\rho_{\text{DT}}} \leq 1 - e^{-r/\lambda_L}. \tag{A.13}
\]
Another application of Eq. (A.12) gives
\[
\lambda_{\text{DT}}(\Omega) < r + d. \tag{A.14}
\]
Together with the fact that \(\lambda_{\text{hit}}(\Omega) = d\), we finally have
\[
\frac{\delta [\lambda_{\text{hit}}]}{\lambda_{\text{hit}}} = 1 - \frac{\lambda_{\text{hit}}(\Omega)}{\lambda_{\text{hit}}(\Omega)} \leq \frac{r}{r + d}. \tag{A.15}
\]

APPENDIX B: DIFFUSIVE TRANSPORT TO IDEALIZED TARGETS

In this section, we present the computation for the Laplace transform of the non-dimensionalized flux to the two idealized targets discussed in Sect. III.

1. Disk-shaped target

First, we consider the disk which is centered at the origin with radius \(r_0 = r/d\). Then one can naturally set the source location \(x_{s,0} = (R_0, 0)\) where \(R_0 = 1 + r_0\). One interesting observation is that the total concentration flux only depends on the distance to the source
\[
J_{\text{diff},0}(t_0; x_{s,0}(y)) \equiv J_{\text{diff},0}(t_0; R_0 - r_0),
\]
where \(x_{s,0}(y)\) is the source location parameterized by the arc length over the circle with radius \(R_0\) and \(x_{s,0}(0) = (R_0, 0)\). In order to use this symmetry, we introduce the averaged concentration
\[
\bar{u}(x_0, t_0) = \frac{1}{2\pi R_0} \int_0^{2\pi R_0} u_0(x_0, t_0; x_{s,0}(y)) dy.
\]
Averaging the non-dimensionalized Eq. (III.1) gives
\[
\frac{\partial \bar{u}}{\partial t} = \nabla^2 \bar{u} - g_0 \bar{u} + \frac{1}{2\pi R_0} \int_0^{2\pi R_0} \delta(x_0 - x_{s,0}(y)) dy. \tag{B.1}
\]
Multiplying the smooth test function and performing integration by parts, one can show that it is equivalent to solve the equation in the polar coordinate
\[
\frac{\partial \bar{u}}{\partial t} = \frac{1}{r} \frac{\partial}{\partial r} \left( r \frac{\partial \bar{u}}{\partial r} \right) - g_0 \bar{u}, \tag{B.2}
\]
together with the boundary conditions
\[
\bar{u}(r_0, t_0) = 0, \quad \lim_{r \to \infty} \bar{u}(r, t_0) = 0, \tag{B.3}
\]
the jump condition induced from the delta function
\[
[\bar{u}]^+ = 0, \quad \left[ \frac{\partial \bar{u}}{\partial r} \right]^+ = -\frac{1}{2\pi R_0}, \tag{B.4}
\]
where \([f(r)]^+ = \lim_{r \to R_0^+} f(r) - \lim_{r \to R_0^-} f(r)\). Taking the Laplace transform gives
\[
sL[\bar{u}](r, s) = \frac{1}{r} \frac{\partial}{\partial r} \left( r \frac{\partial L[\bar{u}]}{\partial r} \right) - g_0 L[\bar{u}], \tag{B.5}
\]
whose general solution takes the form of
\[
L[\bar{u}](r, s) = A(s) I_0(r \sqrt{s + g_0}) + B(s) K_0(r \sqrt{s + g_0}),
\]
where \(I_\beta, K_\beta\) are the modified Bessel functions of the first and the second kind with order \(\beta\), respectively. Matching the coefficients with the conditions
\[
L[\bar{u}](r_0, s) = 0, \quad \lim_{r \to \infty} L[\bar{u}](r, s) = 0, \tag{B.6a}
\]
\[
\left[ L[\bar{u}] \right]^+ = 0, \quad \left[ \frac{\partial L[\bar{u}]}{\partial r} \right]^+ = -\frac{1}{2\pi R_0 s}, \tag{B.6b}
\]
one can determine the solution
\[
L[\bar{u}](r, s) = \begin{cases} 
A_{-}(s) I_0(r \sqrt{s + g_0}) + B_{-}(s) K_0(r \sqrt{s + g_0}), & r \leq R_0 \\
B_{+}(s) K_0(r \sqrt{s + g_0}), & r > R_0
\end{cases}
\]
where
\[ A_-(s) = K_0(r_0 \sqrt{s + g_0})Q(s), \]
\[ B_-(s) = -I_0(r_0 \sqrt{s + g_0})Q(s), \]
\[ B_+(s) = A_-(s)I_0(R_0 \sqrt{s + g_0})/K_0(R_0 \sqrt{s + g_0}) + B_-(s) \]
and
\[ Q(s) = \frac{K_0(R_0 \sqrt{s + g_0})}{2\pi s K_0(r_0 \sqrt{s + g_0})}. \]

Then the Laplace transformation of the flux is
\[ \mathcal{L}[J_{\text{diff,0}}](s) = 2\pi r_0 \frac{\partial \mathcal{L}[u]}{\partial r} \bigg|_{r=r_0} \]
\[ = \frac{K_0(R_0 \sqrt{g_0})}{s K_0(r_0 \sqrt{g_0})}. \tag{B.7} \]

This yields
\[ J_{\text{diff,0}}^{\text{ss}} = \lim_{s \to 0} s \mathcal{L}[J_{\text{diff,0}}](s) \]
\[ = \frac{K_0(R_0 \sqrt{g_0})}{K_0(r_0 \sqrt{g_0})}. \tag{B.8} \]

This determines the coefficient \( \Psi_{\text{diff}} \) in Eq. (III.8)
\[ \Psi_{\text{diff}} = 2 \lim_{s \to 0} \frac{1}{s} - \frac{\mathcal{L}[J_{\text{diff,0}}](s)}{\rho_{\text{diff}}} \]
\[ = F_K(1 + r_0, g_0) - F_K(r_0, g_0), \tag{B.9} \]
where \( F_K(x, y) = x K_1(x \sqrt{y})/(\sqrt{y} K_0(x \sqrt{y})) \).

2. Annulus-shaped target

Next, we solve the non-dimensional diffusion equation for the annulus-shaped target together with the source located at the center. That is, the concentration dynamics is governed by
\[ \frac{\partial u_0}{\partial t_0} = \nabla^2 u_0 - g_0 u_0 + \delta(x_0), \tag{B.10} \]
which is supplemented by the absorbing boundary condition
\[ u(|x_0| = 1, t_0) = 0. \tag{B.11} \]

Using a test function argument, one can derive an equivalent equation without the delta function in the polar coordinate
\[ \frac{\partial u_0}{\partial t_0} = \frac{1}{r} \frac{\partial}{\partial r} \left( r \frac{\partial u_0}{\partial r} \right) - g_0 u_0. \tag{B.12} \]

Together with the boundary conditions
\[ \lim_{r \to 0} r \frac{\partial u_0(r, t_0)}{\partial r} = -\frac{1}{2\pi}, \quad u_0(1, t_0) = 0. \tag{B.13} \]

Taking the Laplace transform in time
\[ s \mathcal{L}[u_0](r, s) = \frac{1}{r} \frac{\partial}{\partial r} \left( r \frac{\partial \mathcal{L}[u_0]}{\partial r} \right) - g_0 \mathcal{L}[u_0]. \tag{B.14} \]

Similar to the previous section, the general solutions takes the form
\[ \mathcal{L}[u_0](r, s) = A(s) I_0(r \sqrt{s + g_0}) + B(s) K_0(r \sqrt{s + g_0}). \]

Determining the coefficients by matching boundary conditions
\[ \lim_{r \to 0} r \frac{\partial \mathcal{L}[u_0]}{\partial r} = -\frac{1}{2\pi s}, \quad \mathcal{L}[u_0](1, s) = 0, \tag{B.15} \]
we have the Laplace transform of the non-dimensional flux
\[ \mathcal{L}[J_{\text{diff,0}}](s) = \frac{1}{s I_0(\sqrt{s + g_0})}. \tag{B.16} \]

This gives the asymptotic flux
\[ J_{\text{diff,0}}^{\text{ss}} = \lim_{s \to 0} s \mathcal{L}[J_{\text{diff,0}}](s) \]
\[ = \frac{1}{I_0(\sqrt{g_0})}. \tag{B.17} \]

Using this, one can also determine the coefficient the coefficient \( \Psi_{\text{diff}} \) in Eq. (III.8)
\[ \Psi_{\text{diff}} = 2 \lim_{s \to 0} \frac{1}{s} - \frac{\mathcal{L}[J_{\text{diff,0}}](s)}{\rho_{\text{diff}}} \]
\[ = F_I(g_0), \tag{B.18} \]
where \( F_I(x) = I_1(\sqrt{x})/(\sqrt{x} I_0(\sqrt{x})) \).
