Abstract

Multistate process data are common in studies of chronic diseases such as cancer. These data are ideal for precision medicine purposes as they can be leveraged to improve more refined health outcomes, compared to standard survival outcomes, as well as incorporate patient preferences regarding quantity versus quality of life. However, there are currently no methods for the estimation of optimal individualized treatment rules with such data. In this article, we propose a nonparametric outcome weighted learning approach for this problem in randomized clinical trial settings. The theoretical properties of the proposed methods, including Fisher consistency and asymptotic normality of the estimated expected outcome under the estimated optimal individualized treatment rule, are rigorously established. A consistent closed-form variance estimator is provided and methodology for the calculation of simultaneous confidence intervals is proposed. Simulation studies show that the proposed methodology and inference procedures work well even with small sample sizes and high rates of right censoring. The methodology is illustrated using data from a randomized clinical trial on the treatment of metastatic squamous-cell carcinoma of the head and neck.

Keywords: Outcome weighted learning; patient preferences; precision medicine; quality-adjusted survival; response.
1 Introduction

Modern precision medicine acknowledges the heterogeneity of the majority of human diseases and aims to develop and deliver therapies that are tailored to the individual patient. At the heart of these efforts is the development of data-driven individualized treatment assignment rules (Kosorok and Laber, 2019). The purpose of such rules is to provide the right treatment to a given patient (Lipkovich et al., 2017) and, thereby, to improve health outcomes among patients overall. Over the past decade there has been a large number of new statistical methods for the estimation of optimal individualized treatment rules (ITRs) with various types of outcomes, including continuous, binary, survival, and competing risks outcomes. However, to the best of our knowledge, there are currently no methods for the estimation of optimal ITRs with stochastic processes that evolve through multiple discrete states over (continuous) time, also known as multistate processes. Such processes are commonly encountered in studies of chronic diseases, such as cancer and HIV infection, where disease evolution is often characterized by multiple discrete health states. An example is the SPECTRUM trial (Vermorken et al., 2013), a phase III randomized clinical trial on recurrent or metastatic squamous-cell carcinoma of the head and neck, where patient event history was characterized by the states “tumor response” (i.e., tumor shrinkage per Therasse et al. (2000)), “disease progression”, and “death”. This paper addresses the issue of optimal ITR estimation with right-censored multistate processes data in randomized clinical trial settings.

Multistate process data are ideal for precision medicine purposes as they can be leveraged to improve more refined health outcomes (compared to, e.g., overall or progression-free survival) as well as incorporate patient preferences. Typically, such data contain information about one or more transient health states (e.g., tumor response) that is not fully captured by standard survival or competing risks data. Therefore, they provide more com-
prehensive information about more refined health outcomes that may reflect both quantity and quality of life. Improvement of such outcomes may be more desirable than mere life extension to both patients and clinicians. In oncology, for example, such a desirable health outcome is sustained tumor response, which is associated with better quality of life, extended progression-free survival, and a prolonged treatment-free interval (Kaufman et al., 2017). Tumor response was also a desirable outcome in the SPECTRUM trial mentioned above. Another important outcome is extended quality-adjusted lifetime, which can be defined as the weighted sum of the times spent in a set of desirable health states (Pelzer et al., 2017; Oza et al., 2020). Quality-adjusted lifetime can be defined in multiple different ways according to patient preferences by using different weighting schemes that reflect the needs of different groups of patients. In this way, individual priorities towards quality versus quantity of life can be taken into account.

The methods for optimal ITR estimation can be classified into two broad categories: (i) backward induction methods such as Q-learning (Murphy, 2005; Zhao et al., 2009) and A-learning (Murphy, 2003; Robins, 2004) and (ii) direct-search methods, also known as policy-search methods, such as outcome weighted learning (Zhao et al., 2012) and value search estimation (Zhang et al., 2012). The first class of methods typically estimates the optimal ITR by modeling either the conditional expectation of the outcome given the covariates (Q-learning) or the interactions between treatment and the covariates (A-learning). The second class of methods estimates the optimal ITR directly by optimizing an appropriate objective function. Given that imposing a realistic model for the conditional mean outcome or the treatment interactions is difficult for general multistate processes, the focus in this article is on direct-search methods. The issue of ITR estimation with survival outcomes has been well addressed in the literature. Zhao et al. (2015) extended the outcome weighted learning framework of Zhao et al. (2012) to situations where the outcome of interest is a right-censored survival time. Estimation in this method relies on a weighted version of support
vector machines (Cortes and Vapnik, 1995). A similar method for ITR estimation with survival outcomes was proposed by Bai et al. (2017). A value search estimation approach for maximizing the \( t \)-year survival probability was developed by Jiang et al. (2017). This method approximates the nonsmooth objective function of the problem by a smooth one using kernel smoothing. Recently, there has also been some interest in the issue of ITR estimation with competing risk outcomes (Zhou et al., 2021; He et al., 2021). Nevertheless, the methods for survival and competing risk outcomes cannot be used for the estimation of optimal ITRs with right-censored multistate processes, as it will be argued in detail in Section 2.

In this work, we extend the outcome weighted learning framework to deal with situations where the outcome of interest is an arbitrary right-censored multistate process. The proposed method does not impose Markov assumptions or model assumptions on the multistate process of interest. The novelty of this paper is twofold. First, we devise a novel objective function which can handle general nonhomogeneous multistate processes and, also, can easily incorporate patient preferences. This objective function depends on a nonparametric estimate of the censoring distribution to account for right censoring. This leads to a weighted classification problem where the weights depend on an estimate of an infinite-dimensional parameter (i.e., the right censoring distribution). Second, in addition to showing Fisher and universal consistency of the proposed method, we establish the asymptotic distribution of the proposed estimator for the expected outcome under the estimated optimal ITR and derive a consistent closed-form variance estimator. Based on our theoretical results, we also propose a method for the calculation of simultaneous confidence intervals over a set of patient preferences to account for multiplicity. Our simulation studies provide evidence that the proposed estimator and inference procedures work well even with small sample sizes and under high rates of right censoring.

The structure of this paper is as follows. Sections 2 and 3 introduce the proposed
methodology and present its theoretical properties, respectively. The finite sample performance of the proposed optimal ITR estimator and inference procedures is evaluated in Section 4. The methodology is illustrated using data from the SPECTRUM trial in Section 5. Finally, the paper concludes with a discussion in Section 6.

2 Methodology

2.1 Notation and data

Consider a multistate process \( \{X(t) : t \in [0, \tau]\} \) with (finite) state space \( S = \{1, \ldots, S\} \), where \( \tau < \infty \) is the maximum observation time. Let \( Z \in \mathcal{Z} \subset \mathbb{R}^p \) denote a vector of baseline covariates that may be related to the effect of treatment on the multistate process of interest. For simplicity, the treatment \( A \) is considered to be a binary variable taking its values in the treatment set \( \{-1, 1\} \). With multistate processes, the goal of treatment is typically to prolong the time spent in a set of desirable health states. Given that some health states may be more desirable than others and that patient preferences may vary, we define the benefit processes

\[
\left\{ Y_w(t) = w'\bar{X}(t) : t \in [0, \tau], w \in W \right\},
\]

where \( \bar{X}(t) = (I\{X(t) = 1\}, \ldots, I\{X(t) = S\})' \), \( w \) is an \( S \)-dimensional vector of preference weights that satisfies \( 0 \leq w \leq 1 \) and the sum of its elements is positive and less than \( S \), and \( W = \{w_1, \ldots, w_M\} \) is a prespecified finite set of preference weight vectors that reflect different patient preferences/priorities. Based on the latter processes, we define the utilities

\[
\int_0^\tau Y_w(t)dm(t), \quad w \in W,
\]

where the integrator function is \( m(t) = t \) and induces the Lebesgue measure on the Borel \( \sigma \)-algebra \( \mathcal{B}([0, \tau]) \). Since \( \int_0^\tau I\{X(t) = j\}dm(t) \) is the time spent in the \( j \)th state during
the time interval \([0, \tau]\), the utilities \(W\) represent weighted sums of the (restricted) times spent in each state. For example, consider the states “initial disease state” (state 1), “tumor response” (state 2), and “disease progression or death” (state 3), in the setting of the SPECTRUM trial mentioned in the Introduction. A potential choice for the set of preference weights in this example is \(W = \{(0, 1, 0)', (0.5, 1, 0)', (1, 1, 0)\}'\). When \(w = (0, 1, 0)'\), the utility \(\int_0^\tau Y_w(t)dm(t) = \int_0^\tau I\{X(t) = 2\}dm(t)\) corresponds to the restricted time spent in the tumor response state. The utility under the choice \(w = (0.5, 1, 0)'\) corresponds to the restricted quality-adjusted lifetime

\[
\int_0^\tau Y_w(t)dm(t) = 0.5 \times \int_0^\tau I\{X(t) = 1\}dm(t) + \int_0^\tau I\{X(t) = 2\}dm(t).
\]

This utility represents the restricted (quality-adjusted) time lived, where the time spent in the initial disease state (i.e., without tumor response) is reduced by 50% to reflect a quality of life loss due to disease symptoms and/or side effects due to treatment continuation. When \(w = (1, 1, 0)'\), the utility is the (restricted) progression-free survival time, in which the times lived in the initial disease state and the tumor response state are equally important. Different choices of \(w\) reflect different patient priorities towards quality versus quantity of life.

In practice, the multistate and benefit processes are not fully observed for all individuals under observation due to the usual right censoring. For such situations, let \(C\) denote the right censoring time and \(T\) the time of arrival at an absorbing state (i.e., death). The observed data consist of independent and identically distributed copies of

\[
D_i = (Z_i, A_i, \tilde{T}_i, \Delta_i, \{X_i(t)I(C_i \geq \tilde{T}_i \land t) : t \in [0, \tau]\} : i = 1, \ldots, n,
\]

where \(\tilde{T}_i = T_i \land C_i \land \tau\), with \(a \land b = \min(a, b)\) for any \(a, b \in \mathbb{R}\), \(\Delta_i = I(T_i \leq C_i)\), and \(X_i(t)I(C_i \geq T_i \land t), t \in [0, \tau]\), is the right-censored version of the multistate process which is equal to 0 for the right-censored individuals after their right censoring time.
It is important to note that standard methods for right-censored survival and competing risks data cannot be used for the analysis of the utilities under right censoring. This is because the observed utility for a multistate process is
\[
\int_0^\tau Y_w(t)I(C \geq T \wedge t)dm(t) = \int_0^\tau Y_w(t)dm(t) - I(C < T) \int_0^\tau Y_w(t)I(C < t)dm(t),
\]
and, thus, the observed utility for right-censored observations (i.e., observations with \( C < T \wedge \tau \)) satisfies
\[
\int_0^\tau Y_w(t)I(C \geq T \wedge t)dm(t) < C,
\]
if \( \int_0^C Y_w(t)dm(t) < C \). The latter inequality occurs when \( Y(\cdot) \) is a non-monotone process (which is typical) or when at least one element of the preference weight vector is not an integer. Therefore, unlike standard right-censored survival and competing risks data, the observed utility can be smaller than the corresponding right censoring time for right-censored observations.

**2.2 Optimal ITR estimation**

An ITR is a deterministic function \( d : Z \mapsto \{-1, 1\} \) which suggests treatment choice \( d(z) \in \{-1, 1\} \) for a patient with covariates \( Z = z \). Since the estimation of an optimal ITR is essentially a causal inference problem, we utilize the potential outcomes causal framework \([\text{Rubin, 2005; Tsiatis et al., 2019}]\). Let \( Y_w^*(t; 1) \) and \( Y_w^*(t; -1) \), \( w \in W \), denote the potential benefit processes under treatment choices 1 and \(-1\), respectively, at time \( t \in [0, \tau] \). Since the potential outcomes cannot be directly observed in real-world settings, we need to impose the following causal assumptions.

A1. Stable unit treatment value assumption: \( Y_w(\cdot) = Y_w^*(\cdot; 1)I(A = 1) + Y_w^*(\cdot; -1)I(A = -1) \).

A2. Independent treatment assignment assumption: \( \{Y_w^*(\cdot; 1), Y_w^*(\cdot; -1)\} \perp \perp A \).
A3. Positivity assumption: \( \pi_0 = P(A = 1) \in [c_1, c_2] \), with \( 0 < c_1 < c_2 < 1 \).

Assumptions A2 and A3 are automatically satisfied in randomized clinical trials. Now, we can define the potential benefit processes under an ITR \( d \) as

\[
Y_w^*(t; d) = Y_w^*(t; 1)I\{d(Z) = 1\} + Y_w^*(t; -1)I\{d(Z) = -1\}, \quad w \in \mathcal{W}, \quad t \in [0, \tau].
\]

These processes are essential for defining potential benefit under an ITR for multistate processes. For such processes, we define the value functions as

\[
V_w(d) = E \left\{ \int_0^\tau Y_{1,w}^*(t; d)dm(t) \right\}, \quad w \in \mathcal{W},
\]

where \( V_w(d) \) is the expected sum of the weighted (under \( w \)) times spent in each state of the process during the time interval \([0, \tau]\), under the ITR \( d \). Under assumptions A1–A3, the independent right censoring assumption, and the fact that

\[
\frac{Y_w(t)I(C \geq T \wedge t)}{\exp\{-\Lambda_0(T \wedge t)\}} = \frac{Y_w(t)I(C \geq T \wedge t)}{\exp\{-\Lambda_0(T \wedge t)\}}, \quad t \in [0, \tau], \quad w \in \mathcal{W},
\]

it can be shown that the value functions can be expressed in terms of the observable data as

\[
V_w(d) = E \left[ \int_0^\tau \frac{Y_{1,w}(t)I(C_1 \geq T_1 \wedge t)I(A_1 = d(Z_1))}{\exp\{-\Lambda_0(T_1 \wedge t)\}\{A_1\pi_0 + (1 - A_1)/2\}}dm(t) \right], \quad w \in \mathcal{W},
\]

where \( \Lambda_0(t) \) is the cumulative hazard function of the right censoring variable \( C \) at time \( t \).

An optimal ITR \( d^*_w, w \in \mathcal{W} \), is a maximizer of the corresponding value function, i.e.

\[
d^*_w \in \arg \max_d V_w(d).
\]

Given that any rule \( d : \mathcal{Z} \mapsto \{-1, 1\} \) can be expressed as \( d(z) = \text{sgn}\{f(z)\} \), where \( \text{sgn}(x) = I(x \geq 0) - I(x < 0) \), for some measurable function \( f : \mathcal{Z} \mapsto \mathbb{R} \), and since

\[
V_w(d) = E \left[ \int_0^\tau \frac{Y_{1,w}(t)I(C_1 \geq T_1 \wedge t)}{\exp\{-\Lambda_0(T_1 \wedge t)\}\{A_1\pi_0 + (1 - A_1)/2\}}dm(t) \right] - E \left( \left[ \int_0^\tau \frac{Y_{1,w}(t)I(C_1 \geq T_1 \wedge t)}{\exp\{-\Lambda_0(T_1 \wedge t)\}\{A_1\pi_0 + (1 - A_1)/2\}}dm(t) \right] I(A_1 \neq d(Z_1)) \right),
\]

8
an optimal ITR is $d^*_w = \text{sgn}\{f^*_w(Z)\}$, where $f^*_w$ is a minimizer of the risk function

$$\mathcal{R}_w(f) = \mathbb{E}\left[ \int_0^\tau \frac{Y_{1,w}(t)I(C_1 \geq T_1 \wedge t)}{\exp\{-\Lambda_0(T_1 \wedge t)\}\{A_1\pi_0 + (1 - A_1)/2\}} \, dm(t) \right] I(A_1 \neq \text{sgn}(f(Z_1))) \right)$$

$$\mathcal{R}_w(f) = \mathbb{E}\left[ \int_0^\tau \frac{Y_{1,w}(t)I(C_1 \geq T_1 \wedge t)}{\exp\{-\Lambda_0(T_1 \wedge t)\}\{A_1\pi_0 + (1 - A_1)/2\}} \, dm(t) \right] I(A_1 f(Z_1) < 0) ,$$

over all measurable functions $f : \mathcal{Z} \mapsto \mathbb{R}$. It is not hard to see that

$$\mathcal{V}_w(\text{sgn}(f^*_w)) - \mathcal{V}_w(\text{sgn}(f)) = \mathcal{R}_w(f) - \mathcal{R}_w(f^*_w), \quad w \in \mathcal{W},$$

for any measurable $f$. Minimizing $\mathcal{R}_w(f)$ over all measurable functions is clearly not feasible. Therefore, we will consider minimization over a subset of the class of all measurable functions $f : \mathcal{Z} \mapsto \mathbb{R}$. In particular, we consider either of the following subsets.

- Class of linear functions $\{f(\cdot) = \beta_0 + \langle \beta_1, \cdot \rangle : \beta_0 \in \mathbb{R}, \beta_1 \in \mathbb{R}^p\}$, where $\langle \beta_1, z \rangle = \beta_1'z$.

- Reproducing kernel Hilbert space (RKHS) $\mathcal{H}_k$ with kernel $k$, which is the completion of the space

$$\left\{ f(\cdot) = \sum_{j=1}^m \alpha_j k(\cdot, z_j) : m \in \mathbb{N}, z_j \in \mathcal{Z}, \alpha_j \in \mathbb{R} \right\}.$$

Here we consider the RKHS with the Gaussian kernel, $k(z_1, z_2) = \exp(-\sigma_n^2\|z_1 - z_2\|^2)$, $z_1, z_2 \in \mathcal{Z}$.

Minimizing the empirical version of $\mathcal{R}_w(f)$, over the chosen class $\mathcal{F}$, is challenging because it involves a discontinuous and nonconvex function of $f$. To alleviate, we follow the paradigm of outcome weighting learning (Zhao et al., 2012) and support vector machines (Steinwart and Christmann, 2008) and utilize the surrogate risk

$$\mathcal{R}_{\phi,w}(f) = \mathbb{E}\left[ \int_0^\tau \frac{Y_{1,w}(t)I(C_1 \geq T_1 \wedge t)}{\exp\{-\Lambda_0(T_1 \wedge t)\}\{A_1\pi_0 + (1 - A_1)/2\}} \, dm(t) \right] \phi(A_1 f(Z_1)) \right) ,$$

where $\phi(x) = \max(0, 1 - x)$ is the hinge loss, which is convex in $f$. The cumulative hazard function $\Lambda_0$ of the right censoring distribution can be estimated using the nonparametric
Nelson–Aalen estimator
\[
\hat{\Lambda}_n(t) = \int_0^t \frac{\sum_{i=1}^n dN_i(u)}{\sum_{i=1}^n Y_i(u)}, \quad t \in [0, \tau],
\]
where \( N_i(t) = (1 - \Delta_i) I(\tilde{T}_i \leq t) \) and \( Y_i(t) = I(\tilde{T}_i \geq t) \). An obvious estimator of \( \pi_0 \) is \( \hat{\pi}_n = n^{-1} \sum_{i=1}^n I(A_i = 1) \). Thus, the empirical version of the surrogate risk \( \mathcal{R}_{\phi,w} \) is
\[
\hat{\mathcal{R}}_{\phi,w}(f) = \frac{1}{n} \sum_{i=1}^n \left[ \int_0^\tau \frac{Y_{i,w}(t) I(C_i \geq T_i \wedge t)}{\exp\{-\hat{\Lambda}_n(\tilde{T}_i \wedge t)\}} dm(t) \right] \phi(A_i f(Z_i)).
\]
Note that, even though \( \pi_0 \) is typically known in clinical trials, using the corresponding estimate \( \hat{\pi}_n \) leads to increased efficiency in inverse probability weighting type estimators \( \text{(Tsiatis et al., 2019)} \). Based on \( \hat{\mathcal{R}}_{\phi,w}, w \in \mathcal{W} \), the estimators of the optimal decision functions within the class \( \mathcal{F} \) are the minimizers
\[
\hat{f}_{n,w,\lambda_n} = \arg \min_{f \in \mathcal{F}} \left\{ \hat{\mathcal{R}}_{\phi,w}(f) + \lambda_n \|f\|^2 \right\}, \quad w \in \mathcal{W},
\]
where \( \lambda_n \) is a positive tuning parameter that controls the complexity of \( f \) and \( \| \cdot \| \) is a norm on the chosen class \( \mathcal{F} \). For example, \( \| \cdot \| \) is the Euclidean norm if \( \mathcal{F} \) is the class of linear functions. For notational simplicity we omit the subscript \( \lambda_n \) from the estimated decision functions and use the more compact notation \( \hat{f}_{n,w} \). Based on the estimated decision functions \( \{ \hat{f}_{n,w} : w \in \mathcal{W} \} \) the estimated optimal ITRs are
\[
\hat{d}_{n,w}(z) = \text{sgn}\{\hat{f}_{n,w}(z)\}, \quad w \in \mathcal{W}, \quad z \in \mathcal{Z}.
\]
Based on the class of estimated ITRs \( \{ \hat{d}_{n,w} : w \in \mathcal{W} \} \), treatment assignment for a given patient utilizes \( \hat{d}_{n,w} \), for the weight vector \( w \) that is closest, with respect to the Euclidean norm, to the preference weight \( w_0 \) that reflects the patient’s own preferences/priorities.

### 2.3 Estimation of the value function

The value function of an ITR \( d \) can be estimated as
\[
\hat{V}_{n,w}(d) = \frac{1}{n} \sum_{i=1}^n \int_0^{\tau} \frac{Y_{i,w}(t) I(C_i \geq T_i \wedge t) I(A_i = d(Z_i))}{\exp\{-\hat{\Lambda}_n(\tilde{T}_i \wedge t)\}} dm(t), \quad w \in \mathcal{W}.
\]
The value $\hat{V}_{n,w}(d)$ can be seen as the (estimated) performance of the ITR $d$ under the preference weight vector $w$. The estimated value of the estimated optimal ITR $\hat{V}_{n,w}(\hat{d}_{n,w})$ is expected to be an over-optimistic estimate of the performance of $\hat{d}_{n,w}$ in a future (out of sample) patient when sample size is small relatively to $p$ or relatively to the complexity of $\mathcal{F}$. This is because the estimator $\hat{V}_{n,w}(\hat{d}_{n,w})$ uses the same set of data $\{D_i : i = 1, \ldots, n\}$, for both the estimation of the optimal ITR and the evaluation of its performance. This phenomenon is similar to the behaviour of the training error in support vector machines (Jiang et al., 2008; Hastie et al., 2009). A better estimate of $\mathcal{V}_w(\hat{d}_{n,w})$ in finite samples is expected to be the jackknife or leave-one-out cross-validation value estimator

$$
\hat{\mathcal{V}}_{jk,n,w}(\hat{d}_{n,w}) = \frac{1}{n} \sum_{i=1}^{n} \int_{0}^{\tau} \frac{Y_{i,w}(t)I(C_i \geq T_i \land t)I(A_i = \hat{d}_{n,w}^{(-i)}(Z_i))}{\exp\{-\Lambda_n(T_i \land t)\}\{A_i\hat{\pi}_n + (1 - A_i)/2\}}dm(t), \quad w \in \mathcal{W},
$$

(2)

where $\hat{d}_{n,w}^{(-i)} = \text{sgn}(\hat{f}_{n,w}^{(-i)})$ is the optimal ITR estimated under the preference weight vector $w$ using all but the data of the $i$th individual.

### 3 Theoretical Properties

Before presenting the theoretical properties of the proposed estimators, we provide a set of regularity conditions.

C1. The potential right censoring time $C$ is independent of the multistate process $\{X(t) : t \in [0, \tau]\}$.

C2. The multistate process has a square-integrable total variation, i.e. $E\{\int_0^\tau |dX(t)|\}^2 < \infty$.

C3. The covariate space $\mathcal{Z}$ is a compact subset of $\mathbb{R}^p$. 

11
C4. The true cumulative baseline hazard $\Lambda_0(t)$ of the right censoring distribution is a continuous function on $[0, \tau]$.

C5. For a linear decision function $\tilde{f}_w(\cdot) = \tilde{\beta}_0, w + \langle \tilde{\beta}_1, w, \cdot \rangle$ that minimizes $R_{\phi,w}(f)$ over the space of linear functions, $(\tilde{\beta}_{0,w}, \tilde{\beta}_{1,w})' \in \mathcal{B} \subset \mathbb{R}^{p+1}$, where $\mathcal{B}$ is a compact and convex set. Moreover,

$$P[A = 1, \{1 - (\tilde{\beta}_{0,w} + \langle \tilde{\beta}_{1,w}, Z \rangle)\}{1 - (\beta_0 + \langle \beta_1, Z \rangle)} < 0]$$

$$+ P[A = -1, \{1 + (\tilde{\beta}_{0,w} + \langle \tilde{\beta}_{1,w}, Z \rangle)\}{1 + (\beta_0 + \langle \beta_1, Z \rangle)} < 0] > 0,$$

for $(\beta_0, \beta_1)' \neq (\tilde{\beta}_{0,w}, \tilde{\beta}_{1,w})'$.

Conditions C1, C2, and C4 are standard in the literature of nonparametric methods for survival and multistate process data. An approach to weaken condition C1 is suggested in the Discussion. Condition C3 is another common condition that ensures that the covariates are bounded. Condition C5 guarantees the uniqueness of the optimal linear decision function $\tilde{f}_w$. This condition has been used previously in the literature of (unweighted) support vector machines (Jiang et al., 2008).

The following result justifies the use of the surrogate risk $R_{\phi,w}$, instead of the original risk $R_w$, for the estimation of optimal ITR $d^*_w$, $w \in \mathcal{W}$.

**Theorem 1** (Fisher consistency). Suppose that assumptions A1–A3 and condition C1 hold. Then, for any $w \in \mathcal{W}$, if $\tilde{f}_w$ minimizes $R_{\phi,w}$, $d^*_w(z) = \text{sgn}\{\tilde{f}_w(z)\}$ for all $z \in \mathcal{Z}$.

The proof of Theorem 1 can be found in Appendix A.1. The next theorem ensures that $R_{\phi,w}(\tilde{f}_{n,w})$, which is the true surrogate risk of the estimated decision function $\tilde{f}_{n,w}$, converges (in probability) to the minimal surrogate risk over the chosen class $\mathcal{F}$. It also asserts that, if the chosen class $\mathcal{F}$ is appropriate, then the proposed estimator $\hat{d}_{n,w}$ is universally consistent, i.e., its value converges (in probability) to the optimal value $V_w(d^*_w)$.
Theorem 2. Suppose that assumptions A1–A3 and conditions C1, C3, and C4 hold. Then, for \( \lambda_n > 0 \) with \( \lambda_n \to 0 \), and \( n\lambda_n \to \infty \),

\[
\left| \mathcal{R}_{\phi,w}(\hat{f}_{n,w}) - \inf_{f \in \mathcal{F}} \mathcal{R}_{\phi,w}(f) \right| \xrightarrow{p} 0, \quad w \in \mathcal{W},
\]
as \( n \to \infty \), for any distribution \( P \) of the data \( D \). Moreover, if (i) \( \mathcal{F} \) is the space of linear functions and \( f^*_w \in \mathcal{F} \) or (ii) \( \mathcal{F} \) is the RKHS with the Gaussian kernel and the marginal distribution \( \mu \) of \( Z \) is regular, then

\[
\left| \mathcal{V}_{w}(d_{n,w}) - \mathcal{V}_{w}(d^*_w) \right| \xrightarrow{p} 0,
\]
as \( n \to \infty \).

Theorem 2 is proved in Appendix A.2. When \( \mathcal{F} \) is the space of linear functions, universal consistency requires that the optimal decision function \( f^*_w \) is linear, i.e. \( f^*_w \in \mathcal{F} \). This requirement can be made more plausible by considering an enlarged covariate space \( \tilde{Z} \) that includes polynomial terms and/or two-way interaction terms between the original covariates \( Z \). If \( f^*_w \notin \mathcal{F} \), \( \mathcal{V}_w(\hat{d}_{n,w}) \) is expected to converge to a value that is lower than the optimal value \( \mathcal{V}_w(d^*_w) \). Nevertheless, the limit of \( \mathcal{V}_w(\hat{d}_{n,w}) \) can be seen as an approximation to the optimal value \( \mathcal{V}_w(d^*_w) \) by the first statement of Theorem 2 and the fact that \( \mathcal{R}_w(f^*_w) \leq \mathcal{R}_w(f) \leq \mathcal{R}_{\phi,w}(f) \) for any \( f \in \mathcal{F} \), since the hinge loss satisfies \( \phi(x) \geq I(x < 0) \) for all \( x \in \mathbb{R} \).

Interestingly, when \( \mathcal{F} \) is the RKHS with the Gaussian kernel and the marginal distribution of \( Z \) is regular, the estimated ITR is always universally consistent. However, the so-called no-free-lunch theorem [Steinwart and Christmann, 2008] implies that the corresponding rate of convergence can be extremely slow for at least some distributions of the data. This means that an extremely large sample size may be required in practice in order to obtain an ITR \( \hat{d}_{n,w} \) with a value reasonably close to the optimal value. For this reason, we will restrict our attention to the case where \( \mathcal{F} \) is the space of linear functions in the remainder of this paper.
The next theorem characterizes the asymptotic distribution of the estimated value function of a fixed decision function $f$. Before stating the theorem we introduce some further notation. First, define the fixed function

$$\eta'_{\Lambda_0,f,w}(h) = E \left\{ \int_0^T Y_{1,w}(t) I(C_1 \geq T_1 \wedge t) I[A_1 = \text{sgn}\{f(Z_1)\}] h(T_1 \wedge t) dm(t) \right\},$$

where $h$ is any non-decreasing right continuous function on $[0, \tau]$ with left hand limits. In Appendix A.3 it is argued that $\eta'_{\Lambda_0,f,w}(h)$ is the Hadamard derivative of the (true) value function of the ITR $\text{sgn}\{f(z)\}$ at $\Lambda_0$, under the weight $w$. Also, define the random functions

$$\gamma_i(t) = \int_0^t dN_i(s) - \int_0^t \frac{Y_i(s)}{EY_1(s)} d\Lambda_0(s), \quad i = 1, \ldots, n, \quad t \in [0, \tau],$$

and

$$\psi_{i,w}(f) = \int_0^T Y_{i,w}(t) I(C_i \geq T_i \wedge t) I[A_i = \text{sgn}\{f(Z_i)\}] dm(t) - V_{w}(\text{sgn}(f))$$

$$- E \left\{ A_1 \int_0^T Y_{i,w}(t) I(C_i \geq T_i \wedge t) I[A_1 = \text{sgn}\{f(Z_1)\}] dm(t) \right\} \left\{ I(A_i = 1) - \pi_0 \right\}$$

$$+ \eta'_{\Lambda_0,f,w}(\gamma_i), \quad i = 1, \ldots, n, \quad w \in W, \quad f \in \mathcal{F}.$$ 

**Theorem 3.** Under assumptions A1–A3 and conditions C1, C2, and C4, we have that

$$G_{n,w}(f) := \sqrt{n} \left\{ \hat{V}_{n,w}(\text{sgn}(f)) - V_{w}(\text{sgn}(f)) \right\} = \frac{1}{\sqrt{n}} \sum_{i=1}^n \psi_{i,w}(f) + \epsilon_{n,w}(f), \quad w \in W,$$

for any given measurable decision function $f$, where $\epsilon_{n,w}(f) = o_p(1)$. Moreover, if $\mathcal{F}$ is the space of linear functions, then $\sup_{f \in \mathcal{F}} |\epsilon_{n,w}(f)| = o_p(1)$ and the class of influence functions $\{\psi_{w}(f) : f \in \mathcal{F}\}$ is $P$-Donsker.

The proof of Theorem 3 is given in Appendix A.3. This theorem implies that, for any measurable decision function $f$, $G_{n,w}(f)$ is asymptotically normal with mean zero and variance $\sigma_w^2(f) = E\psi_{1,w}^2(f)$. This asymptotic variance can be consistently (in probability)
estimated by \( \hat{\sigma}_w^2(f) = n^{-1} \sum_{i=1}^n \hat{\psi}_{i,w}^2(f) \), where \( \hat{\psi}_{i,w}(f) \), \( i = 1, \ldots, n \), are the empirical versions of the influence functions. The latter are obtained by replacing expectations by sample averages and unknown parameters by their consistent estimates in \( \psi_{i,w}(f) \). The explicit formula for the empirical version of the influence function is provided in Appendix B.

The final theorem characterizes the asymptotic distribution of the estimated value function of \( \hat{d}_{n,w} = \text{sgn}(\hat{f}_{n,w}) \) and provides the basis for the calculation of simultaneous confidence intervals over the preference weight set \( \mathcal{W} = \{w_1, \ldots, w_M\} \).

**Theorem 4.** Suppose that \( \mathcal{F} \) is the space of linear functions. Then, under assumptions A1–A3, conditions C1–C5, the additional assumption that \( P(\tilde{f}_w(Z) = 0) = 0 \), \( w \in \mathcal{W} \), and for \( \lambda_n > 0 \) with \( \lambda_n \to 0 \) and \( n\lambda_n \to \infty \), we have that

\[
\max_{w \in \mathcal{W}} \left| G_{n,w}(\hat{f}_{n,w}) - G_{n,w}(\tilde{f}_w) \right| = o_p(1).
\]

The proof of Theorem 4 is given in Appendix A.4. The last theorem and Theorem 3 imply that \( G_{n,w}(\hat{f}_{n,w}) \) is asymptotically normal with zero mean and variance \( \hat{\sigma}_w^2(\tilde{f}_w) \). This variance can be consistently (in probability) estimated by \( \hat{\sigma}_w^2(\hat{f}_{n,w}) = n^{-1} \sum_{i=1}^n \hat{\psi}_{i,w}^2(\hat{f}_{n,w}) \).

This result can be used for the calculation of (pointwise) confidence intervals and conducting hypothesis testing regarding the performance of the estimated ITR \( \mathcal{V}_w(\text{sgn}(\hat{f}_{n,w})) \) under the preference weight \( w \). Theorems 3 and 4 can also be used for simultaneous inference. Define the vector \( G_n := (G_{n,w_1}(\hat{f}_{n,w_1}), \ldots, G_{n,w_M}(\hat{f}_{n,w_M}))' \) and let \( \|x\|_\infty := \max_{1 \leq l \leq M} |x_l| \) denote the maximum norm of a vector \( x = (x_1, \ldots, x_M)' \in \mathbb{R}^M \). Theorems 3 and 4, the Cramér–Wold theorem, and the continuous mapping theorem, imply that, for any fixed matrix \( Q \) (of appropriate dimension),

\[
\|QG_n\|_\infty \overset{d}{\to} \|QG\|_\infty,
\]

where \( G \sim N(0, \Omega) \), with \( \Omega \) being a positive semidefinite matrix with elements \( \omega_{l,l} = \sigma_{w_l}^2(\tilde{f}_{w_l}) \), \( l = 1, \ldots, M \), and \( \omega_{l,l'} = E\{\psi_{1,w_l}(\tilde{f}_{w_l})\psi_{1,w_{l'}}(\tilde{f}_{w_{l'}})\}, l \neq l' \). The covariance matrix

15
Ω can be consistently (in probability) estimated by the matrix \( \hat{\Omega}_n \) with elements \( \hat{\omega}_{l,l} = \hat{\sigma}_w^{-2}(\hat{f}_{n,w}), l = 1, \ldots, M \), and \( \hat{\omega}_{l,l'} = n^{-1} \sum_{i=1}^{n} \hat{\psi}_{i,w}(\hat{f}_{n,w}) \hat{\psi}_{i,w'}(\hat{f}_{n,w'}), l \neq l' \). Setting \( Q = \text{diag}(\sigma_{w_1}^{-1}(\tilde{f}_{w_1}), \ldots, \sigma_{w_M}^{-1}(\tilde{f}_{w_M})) \) implies that

\[
\max_{w \in \mathcal{W}} |\sigma_w^{-1}(\tilde{f}_w)G_{n,w}(\hat{f}_{n,w})| \overset{d}{\to} \|QG\|_\infty.
\]

The last result implies that \( 1 - \alpha \) simultaneous confidence intervals over \( \mathcal{W} \), which account for the multiplicity due to considering multiple preference weights, can be calculated as

\[
\left[ \hat{V}_{n,w}(\text{sgn}(\hat{f}_{n,w})) - c_\alpha \frac{\hat{\sigma}_w(\hat{f}_{n,w})}{\sqrt{n}}, \hat{V}_{n,w}(\text{sgn}(\hat{f}_{n,w})) + c_\alpha \frac{\hat{\sigma}_w(\hat{f}_{n,w})}{\sqrt{n}} \right], \quad w \in \mathcal{W},
\]

where \( c_\alpha \) is the \( 1 - \alpha \) percentile of the distribution of \( \|QG\|_\infty \). This percentile can be easily estimated using the following simulation procedure. First, choose a large number \( B \) (say \( B = 1000 \)) and simulate vectors \( G_b \sim N(0, \hat{\Omega}_n) \), for \( b = 1, \ldots, B \). Then, \( c_\alpha \) can be estimated as the empirical \( 1 - \alpha \) percentile of the sample \( \|\hat{Q}_nG_1\|_\infty, \ldots, \|\hat{Q}_nG_B\|_\infty \), where \( \hat{Q}_n = \text{diag}(\hat{\sigma}_{w_1}^{-1}(\tilde{f}_{w_1}), \ldots, \hat{\sigma}_{w_M}^{-1}(\tilde{f}_{w_M})) \). Simultaneous confidence intervals for the differences \( \mathcal{V}_w(\text{sgn}(\hat{f}_{n,w})) - \mathcal{V}_w(1) \) and \( \mathcal{V}_w(\text{sgn}(\hat{f}_{n,w})) - \mathcal{V}_w(-1), w \in \mathcal{W} \), where \( \mathcal{V}_w(1) \) and \( \mathcal{V}_w(-1) \) are the value functions for the fixed rules \( d(z) := 1 \) and \( d(z) := -1 \), can be calculated similarly by expanding the vector \( G_n \) to include \( G_{n,w}(1) \) and \( G_{n,w}(-1), w \in \mathcal{W} \), and using an appropriate matrix \( Q \). This is illustrated in the data application presented in Section 5. We argue that the same inference procedures can also be used for the jackknife value estimator \( \hat{V}_{n,w}^{jk}(\text{sgn}(\hat{f}_{n,w})), w \in \mathcal{W} \). This statement is justified numerically in the simulation studies.

4 Simulation Studies

The finite sample performance of the proposed methods was evaluated in a series of simulation experiments. Specifically, we assessed the performance of (i) the proposed ITR
estimator $\hat{d}_{n,w}$ and (ii) the proposed inference methods for the (true) value of the estimated ITR $Y_w(\hat{d}_{n,w})$. We considered a binary treatment variable $A \in \{-1, 1\}$, a two-dimensional covariate vector $Z = (Z_1, Z_2)'$, and a multistate process $\{X(t) : t \in [0, \tau]\}$ under a progressive illness-death model with state space $S = \{1, 2, 3\}$. State 1 represented the initial disease state, state 2 the tumor response state, and state 3 the disease progression or death state, in a hypothetical oncology trial. For simplicity, we considered the single preference weight $w = (0, 1, 0)'$, under which the utility corresponds to the restricted mean duration of tumor response. Treatment was simulated with $P(A = 1) = 0.5$, while the covariates were simulated from the uniform distribution $U(-1, 1)$. The multistate process was simulated, conditionally on $A$ and $Z$, based on the transition intensities $\alpha_{12}(A, Z) = \exp(-0.5Z_1 + 0.5Z_2 + Af_w^*(Z))$, $\alpha_{13}(A, Z) = \exp(-0.5Z_1 + 0.5Z_2)/4$, and $\alpha_{23}(A, Z) = \exp(-0.5Z_1 + 0.5Z_2 - Af_w^*(Z))/2$, where $\alpha_{hj}(a, z)$ represents the transition rate from state $h$ to state $j$ for a patient with $(A, Z)' = (a, z)’$ and $f_w^*$ is the optimal decision function under the preference weight $w = (0, 1, 0)'$. In this simulation study we considered four scenarios according to the form of the optimal decision function as follows:

- Scenario 1: $f_w^*(Z) = Z_1 + Z_2$
- Scenario 2: $f_w^*(Z) = 2(Z_1 - Z_2)$
- Scenario 3: $f_w^*(Z) = 1 + Z_2 - \exp(-Z_1)$
- Scenario 4: $f_w^*(Z) = 2 \log(2 - Z_1 - Z_2) - 1.4$

The right censoring time was simulated independently of the multistate process from the exponential distribution $\text{Exp}(\theta)$, with $\theta \in \{-1.6, -1, -0.4\}$. These choices for $\theta$ led on average to 29.5%, 45.1%, and 62.4% right-censored observations, respectively.

For each scenario and censoring rate $\theta$, we considered the training sample sizes $n \in \{100, 200, 300, 400\}$ and repeated the simulation 1000 times. In each training data set we
applied the proposed method with the search space $\mathcal{F}$ being the space of linear functions. Note that, $f^*_w \notin \mathcal{F}$ in scenarios 3 and 4. The tuning parameter was set to $\lambda_n = n^{-1/2}$, which satisfies the requirements of Theorems 2 and 4. To evaluate the performance of the estimated ITR $\hat{d}_{n,w}$, we considered two metrics: (i) the estimated ITR value ratio $\mathcal{V}_w(\hat{d}_{n,w})/\mathcal{V}_w(d^*_w)$, where $d^*_w = \text{sgn}(f^*_w)$ and $\mathcal{V}_w(d^*_w)$ is the maximum possible value, and (ii) the misclassification rate, defined as the proportion of patients which were assigned by $\hat{d}_{n,w}$ to the wrong treatment. An estimated ITR value ratio close to 1 indicates that the performance of $\hat{d}_{n,w}$ is close to optimal. For each simulated training data set, the true value of the estimated ITR $\mathcal{V}_w(\hat{d}_{n,w})$ and the misclassification rate were calculated based on an independently simulated large testing data set of size 10000. To evaluate the validity of the proposed inference methods for $\mathcal{V}_w(\hat{d}_{n,w})$ we considered: (i) the average percent errors of the value function estimators $\hat{\mathcal{V}}_{n,w}(\hat{d}_{n,w})$ and $\hat{\mathcal{V}}_{j,k}(\hat{d}_{n,w})$, defined as

$$\frac{1}{1000} \sum_{b=1}^{1000} \frac{\hat{\mathcal{V}}_{n,w,b}(\hat{d}_{n,w,b}) - \mathcal{V}_w(\hat{d}_{n,w,b})}{\mathcal{V}_w(\hat{d}_{n,w,b})} \times 100$$

$$\frac{1}{1000} \sum_{b=1}^{1000} \frac{\hat{\mathcal{V}}_{j,k}(\hat{d}_{n,w,b}) - \mathcal{V}_w(\hat{d}_{n,w,b})}{\mathcal{V}_w(\hat{d}_{n,w,b})} \times 100,$$

where $\hat{\mathcal{V}}_{n,w,b}$, $\hat{\mathcal{V}}_{j,k}$, and $\hat{d}_{n,w,b}$ are estimates from the $b$th simulated training data set, (ii) the average of the proposed standard error estimates relatively to the Monte Carlo standard deviation of the value estimates, and (iii) the coverage probability of the 95% confidence intervals calculated using the proposed standard error estimator under asymptotic normality (in light of Theorems 3 and 4).

The simulation results regarding the performance of the estimated ITR $\hat{d}_{n,w}$ are depicted in Figure 1. The estimated ITR value ratio was above 0.9 in all cases. Thus, even in Scenarios 3 and 4 where $f^*_w$ is not linear, the performance of the estimated rule was close to optimal. The maximum fixed rule value ratio $\max\{\mathcal{V}_w(1), \mathcal{V}_w(-1)\}/\mathcal{V}_w(d^*_w)$, where $\mathcal{V}_w(1)$ and $\mathcal{V}_w(-1)$ are the values for the fixed rules $d(z) := 1$ and $d(z) := -1$, was close to 0.8 in all cases. This indicates that the estimated ITR $\hat{d}_{n,w}$ can lead to substantially better health outcomes on average compared to fixed, one-size-fits-all, rules. As expected, the
estimated ITR value ratio was higher with larger training sample sizes and lower censoring rates. A similar pattern was observed for the misclassification rate of $\hat{d}_{n,w}$, which was lower for larger training samples and lower censoring rates. The simulation results regarding the validity of the proposed inference methods for $\mathcal{V}_w(\hat{d}_{n,w})$ are summarized in Tables 1 and 2. In all cases, the value estimator $\hat{\mathcal{V}}_{n,w}(\hat{d}_{n,w})$ provided somewhat optimistic estimates of the true value $\mathcal{V}_w(\hat{d}_{n,w})$. However, the percent error was lower than 4% in all cases with a training sample of $n = 400$ (largest sample size considered in these simulation studies). As expected, the percent error of the jackknife value estimator $\hat{\mathcal{V}}_{jk,n,w}(\hat{d}_{n,w})$ was lower than that of $\hat{\mathcal{V}}_{n,w}(\hat{d}_{n,w})$. However, the difference between the two value estimators was smaller for larger training samples and lower censoring rates. The average standard error estimates were close to the corresponding Monte Carlo standard deviation of the estimates and the coverage probabilities close to the nominal level in all cases. These results indicate the consistency of the proposed standard error estimator and support the asymptotic normality result from Theorems 3 and 4. To sum up, our simulation studies provide numerical evidence for the validity of the proposed ITR estimator $\hat{d}_{n,w}$ and inference procedures for $\mathcal{V}_w(\hat{d}_{n,w})$. In addition they suggest that, the performance of the estimated linear ITR $\mathcal{V}_w(\hat{d}_{n,w})$ may be close to optimal, and substantially better that one-size-fits-all type rules, even in cases where the optimal decision function $f_w^*$ is not linear. Finally, the simulation results support the use of the jackknife value estimator $\hat{\mathcal{V}}_{jk,n,w}(\hat{d}_{n,w})$ over $\hat{\mathcal{V}}_{n,w}(\hat{d}_{n,w})$, particularly with smaller training samples and higher censoring rates.

5 SPECTRUM Trial Data Analysis

The proposed methodology was applied to data from the SPECTRUM Trial (Vermorken et al., 2013), a phase III randomized trial on recurrent or metastatic squamous-cell carcinoma of the head and neck. The goal of this trial was to evaluate the effectiveness of the addition
Figure 1: Simulation study: Performance of $\hat{d}_{n,w}$, $w = (0, 1, 0)'$, in terms of estimated ITR value ratio $V_w(\hat{d}_{n,w})/V_w(d_w^*)$ (top row) and misclassification rate (bottom row). The solid grey horizontal lines (top row) correspond to an optimal performance while the dashed grey horizontal lines (top row) correspond to the maximum fixed rule value ratio $\max\{V_w(1), V_w(-1)\}/V_w(d_w^*)$, where $V_w(1)$ and $V_w(-1)$ are the values for the fixed rules $d(z) := 1$ and $d(z) := -1$.

of panitumumab, a fully human monoclonal antibody which inhibits the epidermal growth factor receptor, to chemotherapy as a first-line treatment approach. The data used in this analysis were obtained from [https://www.projectdatasphere.org/](https://www.projectdatasphere.org/) which is maintained by Project Data Sphere and included 520 patients. Of them, 260 patients were randomly assigned to the chemotherapy + panitumumab group \((A = 1)\) while the remaining patients were assigned to the chemotherapy alone group \((A = -1)\). In this trial, tumor response was defined as an at least 30% decrease in the sum of the longest diameter of target lesions according to the Response Evaluation Criteria in Solid Tumors ([Therasse et al., 2000](https://www.projectdatasphere.org/)). Throughout the follow-up period, 138 (26.5%) patients achieved tumor response while 457 (87.9%) experienced a progression of their disease and/or died. Among the latter patients, 120 (26.3%) had achieved tumor response prior to their disease progression or death. The overall median (95% CI) progression-free survival time was 5.59 (5.29, 5.85) months.

In this analysis, we considered the preference weight set

\[
W = \{w_1, w_2, w_3\} = \{(0, 1, 0)', (0.5, 1, 0)', (1, 1, 0)\}'.
\]

As mentioned in Section 2, in this multistate process setup, the utility under the preference weight \(w_1\) corresponds to the restricted mean duration of tumor response, while the choices \(w_2\) and \(w_3\) provide a restricted quality-adjusted lifetime (where the time spent in the initial state is reduced by 50%) and the restricted progression-free survival time, respectively. The covariates considered in this analysis were centered age (in years) at randomization \((Z_\text{age.c})\), indicator that the primary tumor site is hypopharynx \((Z_\text{hyp})\), indicator of history of prior treatment for squamous-cell carcinoma of the head and neck \((Z_\text{trt.hist})\), and indicator that ECOG performance status at baseline indicates symptoms but the patient is ambulatory (vs fully active; \(Z_\text{ECOG}\)). The tuning parameters \(\lambda_{n,w}, w \in W\), were selected from the candidate set \(\{0.001, 0.005, 0.01, 0.1, 0.25, 0.5, 1, 2.5, 5, 10, 20, 50, 100\} \times n^{-1/2}\), where \(n = 520\), using leave-one-out cross validation. All these potential choices for \(\lambda_{n,w}\) satisfy the requirements
of the theorems in Section 3. The estimated optimal decision functions were

\[ \hat{f}_{n,w_1}(z) = -1.32 - 0.54z_{\text{age,c}} + 0.90z_{\text{hyp}} + 1.17z_{\text{trt.hist}} + 0.83z_{\text{ECOG}}, \]

\[ \hat{f}_{n,w_2}(z) \approx -1.40 + 2.00z_{\text{trt.hist}}, \]

and

\[ \hat{f}_{n,w_3}(z) \approx -1.47 + 2.00z_{\text{trt.hist}}, \]

where the absolute values of the estimated coefficients of \( z_{\text{age,c}}, z_{\text{hyp}}, \) and \( z_{\text{ECOG}}, \) in \( \hat{f}_{n,w_2}(z) \)
and \( \hat{f}_{n,w_3}(z) \) were all less than \( 10^{-6} \). The corresponding class of estimated ITRs is \( \{ \hat{d}_{n,w} = \text{sgn}(\hat{f}_{n,w}) : w \in \{w_1, w_2, w_3\} \} \). Clearly, the estimated ITRs \( \hat{d}_{n,w_2} \) and \( \hat{d}_{n,w_3} \) are equivalent and assign chemotherapy+panitumumab (treatment 1) to the patients with a history of prior treatment, and chemotherapy alone (treatment -1) to those without prior treatment. In contrast, the rule \( \hat{d}_{n,w_1} \) is more complicated and accounts for more covariates. Next, we estimated the performances (i.e., value functions) of the estimated optimal ITRs and compared them to those of the fixed, one-size-fits-all, rules \( d(z) := 1 \) (everyone is assigned to chemotherapy+panitumumab) and \( d(z) := -1 \) (everyone is assigned to chemotherapy alone). To account for the multiplicity due to conducting inference about nine parameters in total, we calculated 95% simultaneous confidence intervals using the approach described in Section 3. The percentile \( c_{0.05} \) was estimated based on \( B = 1000 \) simulation replications and the corresponding estimate was \( \hat{c}_{0.05} = 2.59 \). The results from this analysis are summarized in Table 3. The estimated restricted mean (95% CI) potential time in the tumor response state under \( \hat{d}_{n,w_1} \) was 2.570 (1.763, 3.376) months. This time was significantly longer than the corresponding time under the fixed rule \( d(z) := -1 \) [difference (95% CI): 0.826 (0.025, 1.699) months]. The estimated restricted mean (95% CI) potential quality-adjusted lifetime under \( \hat{d}_{n,w_2} \) was 4.999 (4.168, 5.829) months. This time was significantly longer than the corresponding time under the fixed rule \( d(z) := -1 \) [difference (95% CI): 0.949 (0.003,
Finally, the estimated restricted mean (95% CI) potential progression-free survival time under $\hat{d}_{n,w_3}$ was 7.434 (6.377, 8.490) months.

6 Discussion

This article addressed the issue of optimal ITR estimation in randomized clinical trials with right-censored multistate processes. To achieve this, we devised a novel objective function that can handle general nonhomogeneous multistate processes and can easily incorporate patient preferences. Optimization of this objective function was based on the outcome weighted learning framework (Zhao et al., 2012). The proposed method does not impose model assumptions regarding the multistate process of interest or Markov assumptions. The theoretical properties of the proposed method were established and a closed-form variance estimator for the estimated mean outcome under the estimated optimal ITR was derived. Furthermore, we proposed methodology for the calculation of simultaneous confidence intervals for the latter outcome to account for multiplicity (due to, e.g., considering multiple patient preferences). The simulation studies provided numerical evidence for the validity of the proposed ITR estimation approach and inference procedures.

There are two important practical considerations when applying the proposed approach. First, one needs to specify the preference weight set $W$. This can be achieved by subject matter experts (e.g., clinicians) or via a survey in a sample of patients. For a given $W$, the choice of the most appropriate rule within the class of estimated ITRs $\{\hat{d}_{n,w} : w \in W\}$ for a given patient with a preference weight $w_0$ is $\hat{d}_{n,w}$, with $w = \arg\min_{w \in W} \|w - w_0\|$ (i.e., the closest preference weight in the set $W$). Second, the class of decision functions $F$ needs to be chosen. Even though the proposed ITR estimator is universally consistent when $F$ is the RKHS with the Gaussian kernel, the rate of convergence under this choice may be extremely slow (Steinwart and Christmann, 2008). This means that an extremely large
Table 3: Analysis of the SPECTRUM Trial: Estimated mean potential utilities (i.e., value functions) under the estimated optimal individualized treatment rules $\hat{d}_{n,w}$ for the preference weights $w \in \{(0,1,0)', (0.5,1,0)', (1,1,0)\}'$, and comparison with those under the fixed, one-size-fits-all, rules $d(z) := 1$ (everyone is assigned to chemotherapy+panitumumab) and $d(z) := -1$ (everyone is assigned to chemotherapy alone). The corresponding 95% simultaneous confidence intervals, that adjust for multiplicity due to conducting inference about nine parameters in total, are also provided. ($V_w(\hat{d}_{n,w})$: mean potential utility under $\hat{d}_{n,w}$ for the preference weight $w$; $V_w(1)$: mean potential utility for the preference weight $w$ under the fixed rule $d(z) := 1$; $V_w(-1)$: mean potential utility for the preference weight $w$ under the fixed rule $d(z) := -1$)

</table>
sample size may be needed in practice in order to obtain an ITR $\hat{d}_{n,w}$ whose value $V_w(\hat{d}_{n,w})$ is reasonably close to the optimal value $V_w(d^*_w)$. For this reason, we mainly focused on the class of linear decision functions in most of this article. Under this choice, the proposed estimator is universally consistent only if the true optimal decision function $f^*_w$ is linear. However, even if $f^*_w$ is not linear, the value of the estimated ITR $V_w(\hat{d}_{n,w})$ can be close to the optimal value. This was illustrated in the simulation studies presented in Section 4. In practice, one can further improve the performance of the estimated ITR when $\mathcal{F}$ is the class of linear functions by considering two-way or three-way covariate interactions (Zhou et al., 2017).

A key assumption of the proposed approach is independence between right censoring and the multistate process of interest. This assumption can be weakened by assuming independent right censoring conditional on $Z$. Under this assumption, one can impose a semiparametric Cox model of the form $\Lambda(t; Z) = \Lambda_0(t) \exp(\theta'Z)$ for the right censoring time, and use the estimated conditional hazard in the proposed objective function and value function estimators. Provided that this model is correctly specified, the theoretical properties of the proposed method still hold, with the exception that $\gamma(t)$ in $\psi(f)$ is replaced by the influence function of $\sqrt{n}\{\hat{\Lambda}_n(t) \exp(\hat{\theta}_n'z) - \Lambda(t; z)\}$ under partial likelihood estimation.

There is a number of possible extensions of the work presented in this manuscript. First, addressing the issue of missingness in one or more covariates is crucial in many applications. In the SPECTRUM trial, for example, tumor human papillomavirus (HPV) status was missing for 34.8% of the patients and, thus, it could not be utilized for ITR estimation. Nevertheless, tumor HPV status may be an important predictive factor in patients treated with chemotherapy+panitumumab (Vermorken et al., 2013), and could be utilized to achieve a better performance of the estimated optimal ITRs. Second, another interesting and useful research direction is to allow treatment assignment to depend on the
covariates. This will allow the estimation of ITRs in observational studies with multistate processes where confounding is ubiquitous. Finally, extending the proposed approach for the single-decision problem to the multi-decision setting, such as that encountered in a sequential multiple assignment randomized trial (SMART) [Lavori and Dawson, 2000, 2004], is important from both practical and methodological standpoints.

Appendix A: Proofs

In this Appendix we provide the proofs of the theorems stated in Section 3 of the main text. For notational simplicity, we omit the subscript \( w \), that corresponds to the preference weight, and use the more compact notations \( Y(t) \), \( \mathcal{V}(d) \), \( \hat{V}_n(d) \), \( \hat{f}_n \), \( \hat{d}_n \), and \( \psi(f) \). The proofs of Theorems 2–4 will rely heavily on empirical process theory (??). For these proofs, we will use the standard empirical process theory notation

\[
\mathbb{P}_n f = \frac{1}{n} \sum_{i=1}^{n} f(D_i),
\]

for any measurable function of the data \( f : \mathcal{D} \mapsto \mathbb{R} \), where \( \mathcal{D} \) is the sample space, and

\[
Pf = \int_{\mathcal{D}} f \, dP = E\{f(D)\},
\]

where \( P \) is the true probability measure on the Borel \( \sigma \)-algebra on \( \mathcal{D} \). Furthermore, for any function \( h \) in the space \( D[0, \tau] \) of cadlag functions on \([0, \tau]\), we define the supremum norm \( \|h\|_{[0, \tau]} = \sup_{t \in [0, \tau]} |h(t)| \). Also, we define the class of fixed functions

\[
\mathcal{L}_\delta = \{\Lambda : \Lambda \in D[0, \tau] \text{ and is non-decreasing with } \Lambda(0) = 0, \|\Lambda - \Lambda_0\|_{[0, \tau]} < \delta\},
\]

for some \( \delta > 0 \), and the data-dependent function

\[
\xi_\Lambda(D) = \int_0^\tau Y(t) I(C \geq T \wedge t) \frac{1}{\exp\{-\Lambda(T \wedge t)\}} \, dm(t).
\]

Before providing the proofs of the theorems listed in the main text, we state and prove a useful lemma.

**Lemma 1.** If conditions C2 and C4 are satisfied, then the class of functions \( \{\xi_\Lambda : \Lambda \in \mathcal{L}_\delta\} \) is \( P \)-Donsker.

**Proof.** The class of functions \( \{Y(t) : t \in [0, \tau]\} \) is \( P \)-Donsker as a consequence of condition C2 and Lemma 22.4 in ?. Also, recognizing that

\[
I(C \geq T \wedge t) = 1 - I(C < T)I(C < t),
\]
the class \( \{ I(C \geq T \land t) : t \in [0, \tau] \} \) is \( P \)-Donsker by Lemma 4.1 in (?). Next, see that the class \( \mathcal{L}_\delta \) is uniformly bounded by \( \Lambda_0(\tau) + \delta \), where \( \Lambda_0(\tau) < \infty \) by condition C4, and consider the data-dependent function \( f_\Lambda : D \mapsto [0, \Lambda_0(\tau) + \delta] \) with \( f_\Lambda(D) = \Lambda(\tilde{T}) \), where \( \tilde{T} \in [0, \tau] \) and \( \Lambda \in \mathcal{L}_\delta \). Now, the class \( \{ f_\Lambda : \Lambda \in \mathcal{L}_\delta \} \) is \( P \)-Donsker as a consequence of Lemma 9.11 in ?, as is (trivially) the fixed class \( \{ \Lambda(t) : \Lambda \in \mathcal{L}_\delta, t \in [0, \tau] \} \). Thus, by Corollary 9.32 in ? and the Lipschitz continuity of the exponential function on \([0, \Lambda_0(\tau) + \delta] \), the class \( \{ e^{f_\Lambda \wedge \Lambda(t)} : \Lambda \in \mathcal{L}_\delta, t \in [0, \tau] \} \) is also \( P \)-Donsker. Given that the latter class is uniformly bounded by \( e^{\Lambda_0(\tau) + \delta} \) and that \( \Lambda(\tilde{T} \land t) = \Lambda(\tilde{T}) \land \Lambda(t) \), it follows that the class \( \{ \zeta_{\Lambda,t} : \Lambda \in \mathcal{L}_\delta, t \in [0, \tau] \} \) with

\[
\zeta_{\Lambda,t}(D) = \frac{Y(t)I(C > T \land t)}{\exp\{-\Lambda(\tilde{T} \land t)\}},
\]
is \( P \)-Donsker by virtue of being a product of uniformly bounded \( P \)-Donsker classes. Now, the conclusion of Lemma 1 follows from the fact that

\[
\left| \int_0^\tau \zeta_{\Lambda_1,t}dm(t) - \int_0^\tau \zeta_{\Lambda_2,t}dm(t) \right| \leq \sup_{t \in [0,\tau]} |\zeta_{\Lambda_1,t} - \zeta_{\Lambda_2,t}| \tau,
\]
which implies continuity, and Lemma 15.10 in ?.

\[\Box\]

A.1 Proof of Theorem 1 (Fisher consistency)

Using the same arguments to those used in Tsiatis et al. (2019) for the case of a general ITR, it can be easily shown that the optimal ITR in our case satisfies

\[
d^*(z) = \arg \max_{a \in \{-1,1\}} E \left\{ \int_0^\tau Y_1^*(t; a)dm(t) \mid Z_1 = z \right\}
= \text{sgn} \left[ E \left\{ \int_0^\tau Y_1^*(t; 1)dm(t) \mid Z_1 = z \right\} - E \left\{ \int_0^\tau Y_1^*(t; -1)dm(t) \mid Z_1 = z \right\} \right],
\]
for all \( z \in \mathcal{Z} \). Now, given that

\[
\frac{Y(t)I(C \geq T \land t)}{\exp\{-\Lambda_0(T \land t)\}} = \frac{Y(t)I(C \geq T \land t)}{\exp\{-\Lambda_0(\tilde{T} \land t)\}}, \quad t \in [0, \tau],
\]

33
as argued in the main text, the surrogate risk $\mathcal{R}_\phi$ can be expressed as

$$
\mathcal{R}_\phi(f) = E \left( \int_0^\tau \frac{Y_1(t)I(C_1 \geq T_1 \land t)}{\exp\{-\Lambda_0(T_1 \land t)\} \pi_0} \frac{\phi(A_1 f(Z_1))}{A_1 \pi_0 + (1 - A_1)/2} \right)
$$

$$
+ E \left( \int_0^\tau \frac{Y_1(t)I(C_1 \geq T_1 \land t)}{\exp\{-\Lambda_0(T_1 \land t)\} \pi_0} \frac{I(A_1 = 1) \phi(f(Z_1))}{\pi_0} \right)
$$

By Tonelli’s theorem (?), assumptions A1–A3, and condition C1, we have

$$
\mathcal{R}_\phi(f) = \int_0^\tau E \left[ \frac{Y_1^*(t; 1)I(A_1 = 1)I(C_1 \geq T_1 \land t) \phi(f(Z_1))}{\exp\{-\Lambda_0(T_1 \land t)\} \pi_0} \right] dm(t)
$$

$$
+ \int_0^\tau E \left[ \frac{Y_1^*(t; -1)I(A_1 = -1)I(C_1 \geq T_1 \land t) \phi(-f(Z_1))}{\exp\{-\Lambda_0(T_1 \land t)\} (1 - \pi_0)} \right] dm(t)
$$

$$
= \int_0^\tau E \left[ \frac{Y_1^*(t; 1)I(A_1 = 1)I(C_1 \geq T_1 \land t)}{\exp\{-\Lambda_0(T_1 \land t)\} \pi_0} \right] \frac{\phi(f(Z_1))}{Z_1} dm(t)
$$

$$
+ \int_0^\tau E \left[ \frac{Y_1^*(t; -1)I(A_1 = -1)I(C_1 \geq T_1 \land t)}{\exp\{-\Lambda_0(T_1 \land t)\} \pi_0} \right] \frac{\phi(-f(Z_1))}{Z_1} \frac{1 - \pi_0}{1 - \pi_0} dm(t)
$$

$$
= \int_0^\tau E \left[ \frac{E \{Y_1^*(t; 1)I(C_1 \geq T_1 \land t) \mid T_1, Z_1\}}{\exp\{-\Lambda_0(T_1 \land t)\} \pi_0} \right] \frac{\phi(f(Z_1))}{Z_1} dm(t)
$$

$$
+ \int_0^\tau E \left[ \frac{E \{Y_1^*(t; -1)I(C_1 \geq T_1 \land t) \mid T_1, Z_1\}}{\exp\{-\Lambda_0(T_1 \land t)\} \pi_0} \right] \frac{\phi(-f(Z_1))}{Z_1} \frac{1 - \pi_0}{1 - \pi_0} dm(t)
$$

$$
= E \left\{ \int_0^\tau Y_1^*(t; 1) dm(t) \right\} \frac{\phi(f(Z_1))}{Z_1}
$$

$$
+ E \left\{ \int_0^\tau Y_1^*(t; -1) dm(t) \right\} \frac{\phi(-f(Z_1))}{Z_1}
$$

The function $\tilde{f}$ that minimizes

$$
E \left\{ \int_0^\tau Y_1^*(t; 1) dm(t) \right\} \phi(f(Z_1)) + E \left\{ \int_0^\tau Y_1^*(t; -1) dm(t) \right\} \phi(-f(Z_1))
$$
\[
E \left\{ \int_0^\tau Y_1^*(t; 1) dm(t) \bigg| Z_1 \right\} \max(0, 1 - f(Z_1)) \\
+ E \left\{ \int_0^\tau Y_1^*(t; -1) dm(t) \bigg| Z_1 \right\} \max(0, 1 + f(Z_1)) \\
= E \left\{ \int_0^\tau Y_1^*(t; 1) dm(t) \bigg| Z_1 \right\} \{1 - f(Z_1)\} I(f(Z_1) \leq -1) \\
+ E \left\{ \int_0^\tau Y_1^*(t; -1) dm(t) \bigg| Z_1 \right\} \{1 + f(Z_1)\} I(f(Z_1) \geq 1) \\
+ \left( E \left\{ \int_0^\tau Y_1^*(t; 1) dm(t) \bigg| Z_1 \right\} + E \left\{ \int_0^\tau Y_1^*(t; -1) dm(t) \bigg| Z_1 \right\} \right) f(Z_1) \\
\times I(-1 < f(Z_1) < 1),
\]
also minimizes \( R_\phi \). The latter function is a (continuous) piecewise linear function which decreases strictly on \((-\infty, -1]\) and increases strictly on \([1, \infty)\), almost surely. Therefore, the minimizer should lie in \([-1, 1]\), almost surely. Consequently, for any \( z \in \mathcal{Z} \), if
\[
E \left\{ \int_0^\tau Y_1^*(t; 1) dm(t) \bigg| Z_1 = z \right\} > E \left\{ \int_0^\tau Y_1^*(t; -1) dm(t) \bigg| Z_1 = z \right\},
\]
then \( \tilde{f}(z) \) should be positive, and if
\[
E \left\{ \int_0^\tau Y_1^*(t; 1) dm(t) \bigg| Z_1 = z \right\} < E \left\{ \int_0^\tau Y_1^*(t; -1) dm(t) \bigg| Z_1 = z \right\},
\]
then \( \tilde{f}(z) \) should be negative. Consequently, by (3), \( d^*(z) = \text{sgn}\{\tilde{f}(z)\} \) for all \( z \in \mathcal{Z} \).

### A.2 Proof of Theorem 2

First, define \( g_\pi(D) = A\pi + (1 - A)/2 \) and
\[
L_{f,\Lambda,\pi}(D) = \frac{\xi_\Lambda(D)}{g_\pi(D)} \phi(Af(Z)),
\]
for any \( f \in \mathcal{F} \) (where \( \xi_\Lambda(D) \) was defined in the beginning of Appendix A), and note that \( R_\phi(f) = PL_{f,\Lambda_0,\pi_0} \) and \( \hat{R}_\phi(f) = \mathbb{P}_n L_{f,\hat{\Lambda}_n,\hat{\pi}_n} \). Now, we have that

\[
\frac{Y(t)I(C \geq T \land t)}{\exp\{-\hat{\Lambda}_n(T \land t)\}} \leq \exp\{\hat{\Lambda}_n(T \land t)\} \leq \exp\{\hat{\Lambda}(\tau)\},
\]

for any \( t \in [0, \tau] \) and all \( n \geq 1 \). This fact, along with the uniform (outer) almost sure consistency of the Nelson–Aalen estimator (guaranteed by conditions C1 and C4), the facts that

\[
\int_0^\tau \exp\{\hat{\Lambda}_n(\tau)\} dm(t) = \tau \exp\{\hat{\Lambda}_n(\tau)\} < \infty,
\]

for all \( n \geq 1 \) and

\[
\int_0^\tau \exp\{\Lambda_0(\tau)\} dm(t) = \tau \exp\{\Lambda_0(\tau)\} < \infty,
\]

and the extended dominated convergence theorem (?), lead to the conclusion that \( \xi_{\hat{\Lambda}_n}(D) \xrightarrow{as} \xi_{\Lambda_0}(D) \). This result, the almost sure consistency of \( \hat{\pi}_n \), and the continuous mapping theorem imply that

\[
\max_{1 \leq i \leq n} \frac{\xi_{\hat{\Lambda}_n}(D_i)}{g_{\hat{\pi}_n}(D_i)} - \frac{\xi_{\Lambda_0}(D_i)}{g_{\pi_0}(D_i)} = o_{as}(1). \tag{4}
\]

Consequently,

\[
\sup_{f \in \mathcal{F}} \left\{ \max_{1 \leq i \leq n} \left| L_{f,\hat{\Lambda}_n,\hat{\pi}_n}(D_i) - L_{f,\Lambda_0,\pi_0}(D_i) \right| \right\} = o_{as}(1), \tag{5}
\]

Next, define

\[
\tilde{f} \in \arg\min_{f \in \mathcal{F}} R_\phi(f).
\]

By the positivity of \( \lambda_n \) and the definition of \( \hat{f}_n \), we have that

\[
\mathbb{P}_n L_{\hat{f}_n,\hat{\Lambda}_n,\hat{\pi}_n} \leq \mathbb{P}_n L_{\hat{f}_n,\Lambda_0,\pi_0} + \lambda_n \|\hat{f}_n\|^2 \\
\quad \leq \mathbb{P}_n L_{\hat{f},\Lambda_0,\pi_0} + \lambda_n \|\hat{f}\|^2 \\
= \mathbb{P}_n L_{\hat{f},\Lambda_0,\pi_0} + \lambda_n \|\hat{f}\|^2 + o_{as}(1)
\]
Taking limit superiors in both sides we get
\[
\limsup_{n \to \infty} P_n L_{\hat{f}_n, \hat{\Lambda}_n, \hat{\pi}_n} \leq P L_{\hat{f}, \Lambda_0, \pi_0} = \mathcal{R}_\phi(\hat{f}),
\]
almost surely, by the strong law of large numbers and the fact that \(\lambda_n \to 0\). This implies that, fall all \(n\) sufficiently large,
\[
P_n L_{\hat{f}_n, \hat{\Lambda}_n, \hat{\pi}_n} \leq \mathcal{R}_\phi(\hat{f}) \leq P L_{\hat{f}_n, \Lambda_0, \pi_0} = \mathcal{R}_\phi(\hat{f}_n),
\]
almost surely, by the definition of \(\hat{f}\). Therefore, for all \(n\) sufficiently large, we have
\[
|\mathcal{R}_\phi(\hat{f}_n) - \mathcal{R}_\phi(\hat{f})| \leq \left| P_n L_{\hat{f}_n, \hat{\Lambda}_n, \hat{\pi}_n} - P L_{\hat{f}_n, \Lambda_0, \pi_0} \right|
\leq \left| (P_n - P)L_{\hat{f}_n, \Lambda_0, \pi_0} \right| + \left| P_n L_{\hat{f}_n, \hat{\Lambda}_n, \hat{\pi}_n} - L_{\hat{f}_n, \Lambda_0, \pi_0} \right|
\leq \left| (P_n - P)L_{\hat{f}_n, \Lambda_0, \pi_0} \right| + \delta,
\]  
(6)
amost surely, for any \(\delta > 0\) by (5). Next, it needs to be shown that \((P_n - P)L_{\hat{f}_n, \Lambda_0, \pi_0} = o_p(1)\). By the definition of \(\hat{f}_n\) we have,
\[
P_n L_{\hat{f}_n, \hat{\Lambda}_n, \hat{\pi}_n} + \lambda_n \|\hat{f}_n\|^2 \leq P_n L_{\hat{f}_n, \hat{\Lambda}_n, \hat{\pi}_n} + \lambda_n \|f\|^2,
\]
for any \(f \in \mathcal{F}\). Selecting \(f \equiv 0\), we have
\[
P_n L_{\hat{f}_n, \hat{\Lambda}_n, \hat{\pi}_n} + \lambda_n \|\hat{f}_n\|^2 \leq P_n \frac{\xi_{\hat{\Lambda}_n}}{g_{\hat{\pi}_n}},
\]
since \(\phi(0) = 1\) and \(\|0\| = 0\). By the non-negativity of \(L_{\hat{f}_n, \hat{\Lambda}_n, \hat{\pi}_n}(D)\), the previous inequality implies that
\[
\lambda_n \|\hat{f}_n\|^2 \leq P_n \frac{\xi_{\hat{\Lambda}_n}}{g_{\hat{\pi}_n}} = P_n \frac{\xi_{\hat{\Lambda}_n}}{g_{\pi_0}} + o_{as}(1)
\leq \frac{1}{n} \sum_{i=1}^{n} \frac{\tau \exp\{\Lambda_0(\tau)\}}{A_i \pi_0 + (1 - A_i)/2} + o_{as}(1)
\leq \tau \exp\{\Lambda_0(\tau)\} + o_{as}(1),
\]
by assumption A3. Therefore, for all sufficiently large $n$ and any $\delta' > 0$, we have

$$\lambda_n \| \hat{f}_n \|^2 \leq \frac{\tau \exp\{\Lambda_0(\tau)\}}{c_1 \wedge (1 - c_2)} + \delta' \equiv M_{\delta'},$$

almost surely. Now, the class of functions

$$\mathcal{G}_1(\delta') = \{ \sqrt{\lambda_n} f : f \in \mathcal{F}, \| \sqrt{\lambda_n} f \| \leq \sqrt{M_{\delta'}} \}$$

is Donsker, for any $\delta' > 0$ small. This follows from the fact that if $\mathcal{F}$ is the class of linear or polynomial functions, then $\mathcal{F}$ is Donsker by Lemma 9.6 and Theorem 9.2 in ?, and subsets of Donsker class are also Donsker. If $\mathcal{F}$ is a RKHS, then the $\mathcal{G}_1(\delta')$ is Donsker by condition C3 and similar arguments to those used in the proof of Lemma A.9 in ?. Also, the class

$$\mathcal{G}_2(\delta') = \{ \sqrt{\lambda_n} L f, \Lambda_0, \pi_0 : f \in \mathcal{F}, \| \sqrt{\lambda_n} f \| \leq \sqrt{M_{\delta'}} \}$$

is Donsker by Corollary 9.32 in ?, since $L f, \Lambda_0, \pi_0$ is Lipschitz continuous in $f$, since the hinge loss is Lipschitz continuous in $f$. This implies that, for all $n$ sufficiently large, $\sqrt{\lambda_n} L f, \Lambda_0, \pi_0$ belongs to the Donsker class $\mathcal{G}_2(\delta')$ and therefore

$$\sqrt{n}(\mathbb{P}_n - P) \sqrt{\lambda_n} L f, \Lambda_0, \pi_0 = O_p(1).$$

Consequently,

$$(\mathbb{P}_n - P) L \phi(\hat{f}_n; \Lambda_0, \pi_0) = \frac{1}{\sqrt{n \lambda_n}} O_p(1) = o_p(1),$$

since $n \lambda_n \to \infty$ by assumption. Substituting this result in (6) we have

$$|\mathcal{R}_\phi(\hat{f}_n) - \mathcal{R}_\phi(\tilde{f})| \leq o_p(1) + \delta.$$

Setting $\delta = \delta_n \downarrow 0$, with $\sqrt{n} \delta_n \to \infty$, implies that

$$|\mathcal{R}_\phi(\hat{f}_n) - \mathcal{R}_\phi(\tilde{f})| = o_p(1),$$

38
which completes the proof of the first statement of Theorem 2. For the second statement, it can be shown using similar arguments to those used in the proof of Theorem 3.2 in Zhao et al. (2012) that
\[ R(f) - R(f^*) \leq R_\phi(f) - R_\phi(f^*), \]
for any distribution $P$ of the data $D$ and any measurable decision function $f : \mathcal{Z} \mapsto \mathbb{R}$. Therefore,
\[
\left| V(\hat{d}_n) - V(d^*) \right| = \left| R(\hat{f}_n) - R(f^*) \right| \\
\leq \left| R_\phi(\hat{f}_n) - R_\phi(f^*) \right|.
\]
(7)

Now, if $\mathcal{F}$ is the space of linear functions and $f^* \in \mathcal{F}$, then $\inf_{f \in \mathcal{F}} R_\phi(f) = R_\phi(f^*)$. Thus, consistency follows from the first statement of Theorem 2 and (7). Next, suppose that $\mathcal{F}$ is the RKHS with the Gaussian kernel and that the marginal distribution $\mu$ of $Z$ is regular. Since the Gaussian kernel is a universal kernel, using similar arguments to those used in the proof of Lemma 3.4 in Zhou et al. (2017) leads to
\[
\inf_{f \in \mathcal{F}} R_\phi(f) = R_\phi(f^*). \]
This, (7), and the first statement of Theorem 2 imply universal consistency.

A.3 Proof of Theorem 3

Here we provide the proof of the stronger (uniform) statement of Theorem 3 for the case where $\mathcal{F}$ is the space of linear functions. The proof of the weaker (pointwise) statement for any given measurable function $f$ is a simplified version of the proof below and is not discussed further.

First, note that, for any $f \in \mathcal{F}$, we have
\[
\mathcal{V}(\text{sgn}(f)) = P \frac{\xi_{\Lambda_0}}{g_{\pi_0}} u_f,
\]
where
\[ u_f(D) = I\{A = \text{sgn}(f(Z))\} = I\{Af(Z) \geq 0\}, \]
and
\[ \hat{V}_n(\text{sgn}(f)) = \mathbb{P}_n \frac{\xi_{\hat{\Lambda}_n}}{g_{\pi_n}} u_f. \]

Now, straightforward algebra leads to
\[
\sqrt{n} \left\{ \hat{V}_n(\text{sgn}(f)) - V(\text{sgn}(f)) \right\} = \sqrt{n} \mathbb{P}_n \left( \frac{1}{g_{\pi_n}} - \frac{1}{g_{\pi_0}} \right) (\xi_{\hat{\Lambda}_n} - \xi_{\Lambda_0}) u_f
\]
\[ + \sqrt{n} \mathbb{P}_n \xi_{\Lambda_0} \left( \frac{1}{g_{\pi_n}} - \frac{1}{g_{\pi_0}} \right) u_f \]
\[ + \sqrt{n} \mathbb{P}_n \xi_{\Lambda_0} \left( \frac{1}{g_{\pi_n}} - \frac{1}{g_{\pi_0}} \right) u_f \]
\[ + \sqrt{n} (\mathbb{P}_n - P) \frac{\xi_{\Lambda_0}}{g_{\pi_0}} u_f \]
\[ \equiv B_{n,1}(f) + B_{n,2}(f) + B_{n,3}(f) + B_{n,4}(f) \quad (8) \]

Next, for any functional \( h : \mathcal{F} \mapsto \mathbb{R} \), define the supremum norm \( \|h\|_{\mathcal{F}} = \sup_{f \in \mathcal{F}} |h(f)| \). For the term \( B_{n,1}(f) \) in (8) we have
\[
\|B_{n,1}\|_{\mathcal{F}} \leq \left| \sqrt{n} \mathbb{P}_n \left( \frac{1}{g_{\pi_n}} - \frac{1}{g_{\pi_0}} \right) (\xi_{\hat{\Lambda}_n} - \xi_{\Lambda_0}) \right|
\]
\[ \leq \sqrt{n} \max_{1 \leq i \leq n} \left| \frac{1}{g_{\pi_n}(D_i)} - \frac{1}{g_{\pi_0}(D_i)} \right| \sup_{t \in [0,\tau]} \left| \exp\{\hat{\Lambda}_n(t)\} - \exp\{\Lambda_0(t)\} \right| \tau
\]
\[ \leq \max \left\{ \frac{1}{\hat{\pi}_n \pi_0}, \frac{1}{(1 - \hat{\pi}_n)(1 - \pi_0)} \right\} \sqrt{n} |\hat{\pi}_n - \pi_0| \]
\[ \times \sup_{t \in [0,\tau]} \left| \exp\{\hat{\Lambda}_n(t)\} - \exp\{\Lambda_0(t)\} \right| \tau. \]

The last inequality, along with the boundedness of \( \max\{((\hat{\pi}_n \pi_0)^{-1}, \{(1 - \hat{\pi}_n)(1 - \pi_0)\}^{-1}\} \) for all \( n \) sufficiently large, as a result of assumption A3, the fact that \( \sqrt{n}(\hat{\pi}_n - \pi_0) = O_p(1) \), as a consequence of the central limit theorem, the fact that
\[
\sup_{t \in [0,\tau]} \left| \exp\{\hat{\Lambda}_n(t)\} - \exp\{\Lambda_0(t)\} \right| = o_{\text{ass}}(1),
\]

40
as a result of the strong uniform consistency of the Nelson–Aalen estimator of the cumulative hazard (guaranteed by conditions C1 and C4) and the continuous mapping theorem, and the boundedness of the length of the follow-up interval $\tau$, lead to the conclusion that $\|B_{n,1}\|_{\mathcal{F}} = o_p(1)$.

The term $B_{n,2}(f)$ can be expressed as follows

$$B_{n,2}(f) = \sqrt{n}(\mathbb{P}_n - P)\xi_{\Lambda_n} - \xi_{\Lambda_0}u_f + \sqrt{nP}\frac{\xi_{\Lambda_n} - \xi_{\Lambda_0}}{g_{\pi_0}}u_f.$$  \hspace{1cm} (9)

The class of functions

$$\mathcal{F} = \{ f(\cdot) = \beta_0 + \langle \beta, \cdot \rangle : \beta_0 \in \mathbb{R}, \beta \in \mathbb{R}^p \}$$

is a Vapnik-Červonenkis (VC) class by Lemma 9.6 in ?. This along with lemma 9.9 and theorem 9.2 in ? imply that the class $\{u_f : f \in \mathcal{F} \}$ has bounded uniform entropy integral. In addition, the latter class can be easily argued to be pointwise measurable and, therefore, this class is $P$-Donsker. By conditions C2 and C4 and Lemma 1, the fact that the class $\{\xi_\Lambda : \Lambda \in \mathcal{L}_\delta \}$ is uniformly bounded by $\tau \exp\{\Lambda_0(\tau) + \delta\}$, assumption A3, and the fact that products of uniformly bounded $P$-Donsker classes are also $P$-Donsker, it follows that the class

$$\left\{ \frac{\xi_\Lambda - \xi_{\Lambda_0}}{g_{\pi_0}}u_f : \Lambda \in \mathcal{L}_\delta, f \in \mathcal{F} \right\}$$

is $P$-Donsker for some $\delta > 0$. Also, by assumption A3, we have

$$\sup_{f \in \mathcal{F}} P\left( \left( \frac{\xi_\Lambda - \xi_{\Lambda_0}}{g_{\pi_0}}u_f \right)^2 \right) \leq \frac{\tau \| \exp(\Lambda) - \exp(\Lambda_0)\|_{[0,\tau]}^2}{c_1 \wedge (1 - c_2)} \leq \frac{\tau \exp\{\Lambda_0(\tau)\}\{\exp(\|\Lambda - \Lambda_0\|_{[0,\tau]} - 1)\}^2}{c_1 \wedge (1 - c_2)} \to 0$$

as $\|\Lambda - \Lambda_0\|_{[0,\tau]} \to 0$. The last two results along with the uniform consistency of the Nelson–Aalen estimator, guaranteed by conditions C1 and C4, and arguments similar to those used in the proof of Lemma 3.3.5 in ? lead to the conclusion that

$$\left\| \sqrt{n}(\mathbb{P}_n - P)\frac{\xi_{\Lambda_n} - \xi_{\Lambda_0}}{g_{\pi_0}}u_f \right\|_{\mathcal{F}} = o_p(1).$$
For the second term in the right side of (9), it can be shown that the map \( \Lambda \mapsto P g_{\pi_0}^{-1} \xi_{\Lambda} u_f \) is Hadamard differentiable at \( \Lambda_0 \) with derivative

\[
\eta'_{\Lambda_0, f}(h) = P g_{\pi_0}^{-1} u_f \int_0^\tau Y(t) I(C \geq T \wedge t) \exp\{\Lambda_0(\bar{T} \wedge t)\} h(\bar{T} \wedge t) dm(t).
\]

This, along with the functional delta method (Theorem 3.9.4 in [?]) and the fact that

\[
\sqrt{n} \{ \hat{\Lambda}_n(t) - \Lambda_0(t) \} = \frac{1}{\sqrt{n}} \sum_{i=1}^n \gamma_i(t) + o_p(1), \quad t \in [0, \tau],
\]

where

\[
\gamma_i(t) = \int_0^t \frac{dN_i(s)}{PY(s)} - \int_0^t \frac{Y_i(s)}{PY(s)} d\Lambda_0(s),
\]

lead to the conclusion that

\[
\sqrt{n} P \frac{\xi_{\hat{\Lambda}_n} - \xi_{\Lambda_0}}{g_{\pi_0}} u_f = \frac{1}{\sqrt{n}} \sum_{i=1}^n \eta'_{\Lambda_0, f}(\gamma_i) + o_p(1) + \epsilon_n,1(f)
\]

where \( \gamma_i \) is considered fixed under the expectation operator \( P \). Therefore,

\[
B_{n,2}(f) = \frac{1}{\sqrt{n}} \sum_{i=1}^n \eta'_{\Lambda_0, f}(\gamma_i) + o_p(1) + \epsilon_{n,1}(f)
\]

where

\[
\epsilon_{n,1}(f) = \sqrt{n}(\mathbb{P}_n - P) \frac{\xi_{\hat{\Lambda}_n} - \xi_{\Lambda_0}}{g_{\pi_0}} u_f
\]

with \( \|\epsilon_{n,1}\|_\mathcal{F} = o_p(1) \).
For the term $B_{n,3}(f)$, we have

\[
B_{n,3}(f) = \sqrt{n} \mathbb{P}_n \xi_{\Lambda_0} \left( \frac{1}{g_{\hat{\pi}_n}} - \frac{1}{g_{\pi_0}} \right) u_f
\]

\[
= - \left( \mathbb{P}_n \xi_{\Lambda_0} \frac{A}{g_{\hat{\pi}_n}} u_f \right) \sqrt{n} (\hat{\pi}_n - \pi_0)
\]

\[
= - \left( \mathbb{P}_n \xi_{\Lambda_0} \frac{A}{g_{\hat{\pi}_n}} u_f - P \xi_{\Lambda_0} \frac{A}{g_{\pi_0}} u_f \right) \sqrt{n} (\hat{\pi}_n - \pi_0)
\]

\[
- \left( P \xi_{\Lambda_0} \frac{A}{g_{\pi_0}} u_f \right) \sqrt{n} (\hat{\pi}_n - \pi_0),
\]

where $|\pi_* - \pi_0| \leq |\hat{\pi}_n - \pi_0|$. For the first term in the right side of (10) we have

\[
\sup_{f \in \mathcal{F}} \left| \mathbb{P}_n \xi_{\Lambda_0} \frac{A}{g_{\hat{\pi}_n}} u_f - P \xi_{\Lambda_0} \frac{A}{g_{\pi_0}} u_f \right| \leq \sup_{f \in \mathcal{F}} \left| \mathbb{P}_n \xi_{\Lambda_0} u_f A \left( \frac{1}{g_{\hat{\pi}_n}^2} - \frac{1}{g_{\pi_0}^2} \right) \right|
\]

\[
+ \sup_{f \in \mathcal{F}} \left| (\mathbb{P}_n - P) \xi_{\Lambda_0} \frac{A}{g_{\pi_0}} u_f \right|
\]

\[
\leq \max \left\{ \frac{1}{\pi_*^2} - \frac{1}{\pi_0^2}, \frac{1}{(1 - \pi_*^2)^2} - \frac{1}{(1 - \pi_0)^2} \right\} \tau \exp \{ \Lambda_0(\tau) \}
\]

\[
+ \sup_{f \in \mathcal{F}} \left| (\mathbb{P}_n - P) \xi_{\Lambda_0} \frac{A}{g_{\pi_0}} u_f \right|
\]

The first term in the right side of the above inequality is $o_{as}(1)$ by assumption A3, the fact that $|\pi_* - \pi_0| \leq |\hat{\pi}_n - \pi_0|$, the strong law of large numbers, the continuous mapping theorem, and condition C4, which guarantees the finiteness of $\Lambda_0(\tau)$. The second term in the right side of the last inequality is $o_{as*}(1)$ as a consequence of the $P$-Donsker property of the class

\[
\left\{ \xi_{\Lambda_0} \frac{A}{g_{\pi_0}} u_f : f \in \mathcal{F} \right\},
\]

which follows from similar arguments to those used in the analysis of the term $B_{n,2}(f)$ above, since this property implies that the latter class is also $P$-Glivenko–Cantelli. Therefore, using
the last inequality gives
\[ \sup_{f \in \mathcal{F}} \left| \mathbb{P}_n \xi_{\Lambda_0} \frac{A}{g_{\pi_n}^2} u_f - P \xi_{\Lambda_0} \frac{A}{g_{\pi_0}^2} u_f \right| = o_{a.s.s}(1). \]

Consequently, given that \( \sqrt{n}(\hat{\pi}_n - \pi_0) = \mathcal{O}_p(1) \) by the central limit theorem, it follows from (10) that
\[ B_{n,3}(f) = -\left( P \xi_{\Lambda_0} \frac{A}{g_{\pi_0}^2} u_f \right) \sqrt{n}(\hat{\pi}_n - \pi_0) + \epsilon_{n,2}(f), \]
where
\[ \epsilon_{n,2}(f) = -\left( \mathbb{P}_n \xi_{\Lambda_0} \frac{A}{g_{\pi_n}^2} u_f - P \xi_{\Lambda_0} \frac{A}{g_{\pi_0}^2} u_f \right) \sqrt{n}(\hat{\pi}_n - \pi_0), \]
with \( \|\epsilon_{n,2}\|_\mathcal{F} = o_{a.s.s}(1)\mathcal{O}_p(1) = o_p(1) \).

Taking all the pieces together, it follows from (8) that
\[ \sqrt{n} \left\{ \hat{\mathcal{V}}_n(\text{sgn}(f)) - \mathcal{V}(\text{sgn}(f)) \right\} = \frac{1}{\sqrt{n}} \sum_{i=1}^n \left[ \eta'_{\Lambda_0,f}(\gamma_i) - \left( P \xi_{\Lambda_0} \frac{A}{g_{\pi_0}^2} u_f \right) I(A_i = 1) - \pi_0 \right] + \epsilon_n(f) \]
\[ + \left\{ \frac{\xi_{\Lambda_0}(D_i)}{g_{\pi_0}(D_i)} u_f(D_i) - \mathcal{V}(\text{sgn}(f)) \right\} + \epsilon_n(f), \]
where \( \epsilon_n(f) = B_{n,1}(f) + \epsilon_{n,1}(f) + \epsilon_{n,2}(f) + o_p(1) \) with \( \|\epsilon_n\|_\mathcal{F} = o_p(1) \). Finally, the class of functions \( \{\psi(f) : f \in \mathcal{F}\} \) is \( P \)-Donsker as a consequence of the \( P \)-Donsker property of the class \( \{u_f : f \in \mathcal{F}\} \) as argued above, Lemma 15.10 in ?, and the fact that sums of \( P \)-Donsker classes which are multiplied by random variables with finite second moments are also \( P \)-Donsker.

### A.4 Proof of Theorem 4

Let \( \hat{f}_n(\cdot) = \hat{\beta}_{n,0} + \langle \hat{\beta}_{n,1}, \cdot \rangle \), \( \hat{\beta}_n = (\hat{\beta}_{n,0}, \hat{\beta}'_{n,1})' \) and \( \tilde{\beta} = (\tilde{\beta}_0, \tilde{\beta}'_1)' \). Then, by Theorem 2, condition C5, and similar arguments to those used in Jiang et al. (2008), it follows that
\( \tilde{\beta} \) is unique and \( \| \tilde{\beta} - \beta \|_2 = o_p(1) \), where \( \| \cdot \|_2 \) is the Euclidean norm. Next, using the notation \( f_\beta(\cdot) = \beta_0 + \langle \beta_1', \cdot \rangle \), \( \beta = (\beta_0, \beta_1')' \), Theorem 3 guarantees that the class
\[
\left\{ \psi(f_\beta) - \psi(f_\tilde{\beta}) : \| \beta - \tilde{\beta} \|_2 < \delta \right\}
\]
is \( P \)-Donsker for any \( \delta > 0 \). Moreover, by the assumption that \( P(f_\tilde{\beta}(Z) = 0) = 0 \) which implies the continuity of the map \( \beta \mapsto I(af_\beta(z) \geq 0) \) at \( \tilde{\beta} \) for almost all \( z \in Z \), it follows that
\[
P\{ \psi(f_\beta) - \psi(f_\tilde{\beta}) \}^2 \to 0 \quad \text{as} \quad \beta \to \tilde{\beta}.
\]
Next, by Theorem 3 and arguments similar to those used in the proof of Lemma 3.3.5 in \textit{?}, it follows that
\[
\left| \sqrt{n} \left\{ \hat{V}_n(\text{sgn}(f_\beta)) - \mathcal{V}(\text{sgn}(f_\beta)) \right\} - \sqrt{n} \left\{ \hat{V}_n(\text{sgn}(f_\tilde{\beta})) - \mathcal{V}(\text{sgn}(f_\tilde{\beta})) \right\} \right| = o_p(1),
\]
for any preference weight \( w \) that satisfies the requirements of Section 2 in the main text. Finally, the conclusion of Theorem 4 follows from the last result and the fact that the set \( \mathcal{W} \) of preference weights is finite.

\section*{Appendix B: Empirical Versions of the Influence Functions}

The empirical versions of the influence functions are
\[
\hat{\psi}_{i,w}(f) = \int_0^T \frac{Y_{i,w}(t)I(C_i > T_i \wedge t)I[A_i = \text{sgn}\{f(Z_i)\}]}{\exp\{-\hat{\Lambda}_n(T_i \wedge t)\}\{A_i\hat{\pi}_n + (1 - A_i)/2\}} dm(t) - \hat{V}_{n,w}(\text{sgn}(f))
\end{equation}
\[
- \left\{ \frac{1}{n} \sum_{t=1}^n A_{t} \int_0^T \frac{Y_{i,w}(t)I(C_i > T_i \wedge t)I[A_i = \text{sgn}\{f(Z_i)\}]}{\exp\{-\hat{\Lambda}_n(T_i \wedge t)\}\{A_i\hat{\pi}_n + (1 - A_i)/2\}} dm(t) \right\} \{I(A_i = 1) - \hat{\pi}_n\}
\end{equation}
\[
+ \hat{\eta}'_{\hat{\Lambda}_n,f}(\hat{\gamma}_i), \quad i = 1, \ldots, n, \quad w \in \mathcal{W}, \quad f \in \mathcal{F},
\]
where
\[
\hat{\eta}_{\Lambda_n,f,w}^{(h)}(h) = \frac{1}{n} \sum_{i=1}^{n} \left\{ \int_{0}^{\tau} Y_{i,w}(t) I(C_i > T_i \wedge t) I[A_i = \text{sgn}\{f(Z_i)\}] \exp\{-\Lambda_n(T_i \wedge t)\} \{A_i \hat{\pi}_n + (1 - A_i)/2\} \right. \\
\left. \exp\{-\hat{\Lambda}_n(\tilde{T}_i \wedge t)\} h(T_i \wedge t) dm(t) \right\},
\]
for \( h \in D[0, \tau] \), and
\[
\hat{\gamma}_i(t) = \int_{0}^{t} \frac{dN_i(s)}{n-1 \sum_{j=1}^{n} Y_j(s)} - \int_{0}^{t} \frac{Y_i(s)}{n-1 \sum_{j=1}^{n} Y_j(s)} d\hat{\Lambda}_n(s), \quad i = 1, \ldots, n, \quad t \in [0, \tau].
\]
