ABSTRACT

Scientists frequently prioritize learning from data rather than training the best possible model; however, research in machine learning often prioritizes the latter. The development of marginal feature importance methods, such as marginal contribution feature importance, attempts to break this trend by providing a useful framework for explaining relationships in data in an interpretable fashion. In this work, we generalize the framework of marginal contribution feature importance to improve performance with regards to detecting correlated interactions and reducing runtime. To do so, we consider "information subsets" of the set of features $F$ and show that our importance metric can be computed directly after applying fair representation learning methods from the AI fairness literature. The methods of optimal transport and linear regression are considered and explored experimentally for removing all the information of our feature of interest $f$ from the feature set $F$. Given these implementations, we show on real and simulated data that ultra marginal feature importance performs at least as well as marginal contribution feature importance, with substantially faster computation time and better performance in the presence of correlated interactions and unrelated features.

Keywords Interpretable Machine Learning · Removing Dependencies · Feature Importance · AI Fairness · Fair Representation Learning

1 Introduction

One of the biggest criticisms of machine learning is that it works as a black box. Machine learning models may provide good predictions, but these predictions may not be interpretable. However, utilizers of machine learning methods may also want to understand what is driving a specific prediction and in which ways features are related to each other. This is especially true for problems that have an incomplete problem formalization, such as gaining scientific knowledge in a domain that is not well understood, and when models are related to safety or ethics and have dire consequences [1]. The most widely used framework for peering inside the black box within the field of interpretable machine learning is feature importance.

Unfortunately, feature importance is not well defined and strongly depends on the questions the user seeks to answer [2]. There is not even a complete consensus on how to group different importance measures [3][4]. Though the easiest to understand and the most widely used distinction between feature importance methods is the conditional versus marginal divide. These two groups define the two extremes of feature importance methods [5]. The conditional importance of a feature is defined as the impact of the predictor on the response on top of all other features, whereas marginal importance is defined as the impact of the predictor on the response without taking any other features into account [5]. These definitions may be misconstrued as statements about how interaction effects are dealt with, however these statements are only made in reference to correlated features. Indeed, if all features in a dataset are independent, conditional and marginal importances are exactly the same [5][6]. However, if a feature is dependent on another feature in the model, its conditional importance is lowered since it is now less relevant for predicting the response given the dependent feature, while the marginal importance remains the same [5][6]. Conditional methods are used for feature selection, dimensionality reduction, and improving prediction performance, while marginal methods can be used for explanatory and interpretative purposes [2]. For example, if a scientist wants to build a database of genes associated with some disease, a marginal approach would be preferred [5][4]. Alternatively, if an engineer is interested in obtaining
Ultra Marginal Feature Importance

the smallest number of features to obtain good model predictions, a conditional importance metric is more suitable [2][4]. The conditional versus marginal framework is very similar to the "true to the model" versus "true to the data" framework discussed in [7][8]. In the literature, conditional feature importance methods and methods, which focus on learning about the model, have received more attention compared to marginal methods, which focus on learning from the data [2][5][10][11][12]. In this paper, we will focus on marginal feature importance methods and learning from the data.

Marginal contribution feature importance (MCI) is a recent framework proposed in [7] to measure the marginal importance of a feature. MCI has been shown to work well in simulation studies as well as on real data [7][4][13]. However, there are two shortcomings of MCI. First, MCI underestimates the importance of correlated variables that interact in the expression for the response variable. Second, MCI is given by a maximization problem that requires searching across all subsets of the feature space (F) to calculate exactly, implying exponential run time. These issues are further explained in Section 2.

To overcome these issues, we generalize the MCI framework and introduce ultra marginal feature importance (UMFI). The motivation is to loosen the constraints of the maximization problem such that transformations of F are allowed. We show that the new maximization problem, which maximizes over all "information subsets" of F, is attained only when the information subset is independent of the feature of interest f. Ideally, this would be done in a manner that preserves as much information from the original features as possible. Our framework is presented in Section 3, along with an algorithm to compute the UMFI of a feature f. In Section 5, we show that UMFI can correctly capture the importance of features with correlated interactions without sacrificing performance in other settings compared to MCI.

The most crucial part of the algorithm for UMFI is transforming F \ {f} such that it is mutually independent of the feature of interest f while imposing as little distortion on F \ {f} as possible. The existing literature on removing dependencies among features has largely come from achieving fair or private representations of data. For example, recidivism data in the United States may show that race is correlated with other predictors for recidivism, such as prior arrests [13]. In order to ensure an unbiased estimate from a machine learning model, the training data can be modified to ensure independence from a protected attribute (e.g., age, race, or gender). Though these methods have only been developed for and applied to situations in AI fairness and privacy [15][16][14][17], we demonstrate that they can be useful for solving the optimization problem for UMFI. Methods that have proven useful for these AI fairness and privacy tasks include linear regression [17], optimal transport [14], neural networks [18][19], convex optimization [18], and principal inertial components [15]. We therefore implement two of the aforementioned methods including linear regression and optimal transport to implement and demonstrate UMFI. Both methods for removing dependencies are explained in Section 4, and we discuss their merits and limitations in Section 5 where we discuss the results of our experiments for removing dependencies and computing UMFI.

The goals of this paper are three-fold: (1) we will introduce UMFI and show how it relates to both MCI and fair representation learning, (2) we will demonstrate the usefulness of linear regression and optimal transport for learning fair representations and compare both methods, and (3) we will compare the performance and time complexity of MCI and UMFI on simulated and real data.

2 Overview of Marginal Contribution Feature Importance

Marginal contribution feature importance (MCI) is a state-of-the-art method for measuring feature importance from an "explaining the data" perspective [4][7]. MCI was derived from a set of three desirable axioms that the authors argued a method should have for explaining the data properly. The three axioms include marginal contribution, elimination, and minimalism. The marginal contribution axiom states that the importance of a feature should be greater than or equal to the increase in the evaluation function after adding the feature to the model containing all other features. The elimination axiom states that the importance of a feature can only decrease if features from the feature set are removed. The minimalism axiom states that we should take the minimum feature importance value that satisfies the first two axioms, ensuring its uniqueness.

Let F be the set of features used to predict the response variable, y. Given an evaluation function \( \nu : \mathcal{P}(F) \rightarrow \mathbb{R}^+ \), the authors proved that the Marginal Contribution feature Importance (MCI) score function given by

\[
I_\nu(f) = \max_{S \subseteq F} \nu(S \cup \{f\}) - \nu(S) \tag{2.1}
\]

is the only function that satisfies the three desired axioms mentioned above. The only assumptions that were made on \( \nu \) are that \( \nu(\emptyset) = 0 \) and that \( \nu \) is monotonically increasing. Though these assumptions are not strictly guaranteed when faced with real data, they are reasonable and follow the intuition that more features give a model more information about the response variable. Catav et al. also offered a more concrete definition of \( \nu \) in relation to the expected loss.
reduction between the optimal predictor \( g \in G(S) \), which only uses predictors from \( S \subseteq F \), and the optimal constant predictor \( \hat{y} \) [7]:

\[
\nu(S) = \min_{\hat{y}} \mathbb{E}[l(\hat{y}, y)] - \min_{g \in G(S)} \mathbb{E}[l(g(S), y)].
\]  

(2.2)

Indeed, the axioms provide a powerful foundation on which to build a feature importance method, however, this formulation has three notable downsides. First, the exact computation of \( I_\nu(f) \) is NP-complete and requires \( 2^p \) model trainings, where \( p = |F| \). With just 20 explanatory variables, calculating the exact importance becomes unrealistic on a standard computer. A polynomial runtime is possible given additional assumptions about the order of interactions present in the data, but this is hard to assume and guarantee in practice. Similarly, approximations can be made via randomly sampling from the power set of \( F \), but as demonstrated in one example, the importance scores for 50 features only converges after \( 2^{15} \) iterations [7]. Second, it is unable to find the importance of interactions among dependent or correlated features. This is because when two features are strongly dependent, machine learning models can use just one of these features with little drop in accuracy, so the subset of features, \( S^* \) which maximizes the change in the evaluation function is unable to include strongly dependent features even if interactions exist. Third, MCI may overestimate the importance of features that are unrelated to the response. These shortcomings will be further demonstrated in Section 5.

3 Ultra Marginal Feature Importance

We hypothesize that the maximization function formulated by Catav et al. (2021) is too restrictive. Instead, we propose a maximization over information subsets of \( F \) by using the feature importance metric

\[
U_\nu(f) = \max_{S \subseteq F} \nu(S \cup \{f\}) - \nu(S).
\]  

(3.1)

![Venn diagram illustrating the entropy and mutual information of random variables](image)

Figure 1: Venn diagram illustrating the entropy and mutual information of random variables [20].

Informally, an information subset \( S \subseteq X \) is any subset of the region in the Venn diagram representing \( H(X) \). More precisely, we define the space of information subsets of \( F \) by \( \mathcal{F}(F) = \{ S = g(A) : A \subseteq F \text{ and } g : \mathbb{R}^{|A|} \to \mathbb{R}^{|A|} \} \). Therefore, if \( A = \{ f_1, \ldots, f_m \} \subseteq F \), then we also permit transformations of \( A \) with the form \( S = \{ f_1^*, \ldots, f_m^* \} \subseteq F \). This definition is motivated by the well known fact \( I(Y; g(F)) \leq I(Y; F) \) for any function \( g \) [21, p. 33]. We note that this is essentially the same framework that is used for transforming features to achieve unbiased predictions, such as in [19, 14].

Given this expanded framework, it is easy to see that \( U_\nu(f) \) obeys the marginal contribution and elimination axioms from [7].

**Proof.** Marginal Contribution: \( S = F \setminus \{ f \} \subseteq F \). Hence, \( U_\nu(f) = \max_{S \subseteq F} \nu(S \cup \{f\}) - \nu(S) \geq \nu(F) - \nu(F \setminus \{f\}) \)

Elimination: Let \( T \subseteq F \) and \( \nu : F \setminus T \to \mathbb{R}^+ \) such that \( \nu = \nu : F \setminus T \). Then, for \( f \in F \setminus T \),

\[
U_\nu(f) = \max_{S \subseteq F} \nu(S \cup \{f\}) - \nu(S) \leq \max_{S \subseteq F} \nu(S \cup \{f\}) - \nu(S) = U_\nu(f)
\]

\( \square \)
Ultra Marginal Feature Importance

In addition to \( \nu(\emptyset) = 0 \) and \( \nu \) being monotonically increasing, we also assume that \( \nu \) is supermodular under independence. If \( S, f, X \) are mutually independent random variables, then

\[
\nu(S \cup f) - \nu(S) \leq \nu(S \cup X \cup f) - \nu(S \cup X).
\]

This condition is satisfied when \( \nu \) is defined as mutual information with the response variable \( Y \), i.e. when \( \nu(S) = I(Y; S) \). The result is a simpler version of the result proved in [22, Prop. 2].

**Theorem 3.1.** Let \( S, f, X \) be mutually independent random variables. Then, \( I(Y; S, f, X) - I(Y; S, X) \geq I(Y; S, f) - I(Y; S) \).

**Proof.**

\[
I(Y; S, f, X) - I(Y; S, X) = I(Y; S) + I(Y; X|S) + I(Y; f|S, X) - [I(Y; S) + I(Y; X|S)] \quad \text{(by the chain rule for mutual information)}
\]

\[
= I(Y; f|S, X) = I(Y, S, f | X) \quad \text{(by mutual independence)}
\]

\[
\geq I(Y, S; f) \quad \text{(by monotonicity of } I(\cdot; f)\text{)}
\]

\[
= I(Y; f|S) \quad \text{(by mutual independence)}
\]

\[
= I(Y; S, f) - I(Y; S) \quad \text{(by the chain rule for mutual information)}
\]

\[\square\]

Similarly, we also assume that \( \nu(S) \) is invariant under duplicate information. If \( X \) is completely determined by \( S \), then \( \nu(S \cup X) = \nu(S) \). Again, this is true in the case \( \nu(S) = I(Y; S) \) [23]. Due to the characterization of \( \nu \) from (2.2), and since mutual information and machine learning model evaluation metrics are closely related [24], we believe that \( \nu(S) \) behaves like \( I(Y; S) \) and that these assumptions are therefore justified. Given these suppositions, it is easy to solve for the maximizing subset in (3.1):

\[
S^* = \arg\max_{S \subseteq F} (\nu(S \cup f) - \nu(S)).
\]

**Theorem 3.2.** The maximizing information subset \( S^* \) in (3.2) is given by the largest information subset such that \( S^* \perp \!
\!
\!
\perp f \).

**Proof.** First, suppose for contradiction that \( S^* \) solves (3.2) and that \( S^* \perp \!
\!
\!
\perp f \). Let \( \hat{S} \) represent the remaining information of \( S^* \) after having removed dependencies of \( f \) from \( S^* \). Then, \( \nu(S^* \cup f) = \nu(\hat{S} \cup f) \), but \( \nu(S^* ) \geq \nu(\hat{S} ) \) from monotonicity. Hence, \( \nu(S^* \cup f) - \nu(\hat{S} ) \geq \nu(S^* \cup f) - \nu(S^* ) \), which contradicts the fact that \( S^* \) is the maximizing information subset, so we may assume that \( S^* \perp \!
\!
\!
\perp f \).

Now, suppose that \( S^*, X, f \) are mutually independent information subsets of \( F \). Then, by Theorem 3.1 \( X \) must be included in \( S^* \). Furthermore, because \( \nu \) is assumed to be invariant under duplicate information, then \( S^* \) is satisfied by the largest information subset such that \( S^* \perp \!
\!
\!
\perp f \).

\[\square\]

This key result immediately implies an algorithm for computing the ultra marginal feature importance \( U_\nu(f) = \nu(S^* \cup f) - \nu(S^*) \) of a feature \( f \in F \).

**Algorithm 1:** Algorithm for computing UMFI

**Require:** \( Y = [y_1, \ldots, y_n], f_i = [f_{i1}, \ldots, f_{in}] \) for \( i = 1, \ldots, m \), \( F = [f_1, \ldots, f_m] \).

1. Let \( Y \) be the response variable of the set of predictors \( F \). Choose a feature \( f \in F \).
2. Estimate \( S^* \perp \!
\!
\!
\perp f \) by using a method that removes dependencies on \( f \) from \( F \setminus f \) with minimal information loss.
3. Specify an evaluation function \( \nu \).
4. Train a model using features \( S^* \) to predict \( Y \).
5. Compute \( \nu(S^*) \).
6. Train a model using features \( (S^*, f) \) to predict \( Y \).
7. Compute \( \nu(S^* \cup f) \).
8. return \( U_\nu(f) = \nu(S^* \cup f) - \nu(S^*) \)

The crucial step in this algorithm is the removal of dependencies in step 2. We demonstrate two methods for removing dependencies in the next section.
4 Removing Dependencies

4.1 Optimal Transport

Most of the results and methods explained in this section can be found in [14]. To avoid confusion with the probability density function, we denote a feature \( f \in F \) by \( Z \) and continue this notation in subsequent sections. Let \( X \in F \setminus Z \).

We would like to remove the dependencies of \( Z \) from \( X \) with minimal information loss with respect to \( X \). To do so using optimal transport, we consider the Monge problem:

\[
g_c(X, \tilde{X}) = \inf_{g, g(X) \sim \tilde{X}} \mathbb{E}[c(X, g(X))] = \inf_{g, g(X) \sim \tilde{X}} \int c(x, g(x))d\mu(x). \tag{4.1.1}
\]

The quantity \( g_c(X, \tilde{X}) \) represents the transportation cost of moving \( X \) to \( \tilde{X} \) with respect to some cost function \( c \), and in our case, \( X \perp \!
\!
\perp Z \). It is natural to use \( c(x, \tilde{x}) = d^q(x, \tilde{x}) \), where \( d \) is the Euclidean norm. The transportation cost is also given by the Wasserstein-\( q \) distance, \( g_c(X, \tilde{X}) = \mathcal{W}_q^q(X, \tilde{X}) \), defined below for one-dimensional distributions.

\[
\mathcal{W}_q(X, \tilde{X}) = \int_0^1 |F^{\leftarrow}(p) - \tilde{F}^{\leftarrow}(p)|^qdp,
\]

where \( F \) and \( \tilde{F} \) are the cdfs of \( X \) and \( \tilde{X} \), and \( F^{\leftarrow}(p) = \sup_{x \in \mathbb{R}} F(x) \leq p \). It can be shown that given any continuous one dimensional distributions \( X \) and \( \tilde{X} \), the optimal transport map \( g : X \rightarrow \tilde{X} \) is given by \( g = F^{\leftarrow} \circ F \).

**Theorem 4.1.** Let \( X \) be a r.v. with density \( f \) and cdf \( F \). Let \( \tilde{X} \) have cdf \( \tilde{F} \). Then \( g = F^{\leftarrow} \circ F \) is the minimizer to (4.1.1). Hence, \( g \) optimally transports \( X \) to \( X = F^{\leftarrow}(F(X)) \).

**Proof.** We show \( \mathbb{E}[(X - g(X))^q] = \int_0^1 |F^{\leftarrow}(p) - \tilde{F}^{\leftarrow}(p)|^qdp \) for \( g = F^{\leftarrow} \circ F \).

\[
\mathbb{E}[(X - g(X))^q] = \int_{-\infty}^{\infty} |x - \tilde{F}^{\leftarrow}(F(x))|^q f(x)dx
\]

\[
= \int_{-\infty}^{\infty} |F^{\leftarrow}(F(x)) - \tilde{F}^{\leftarrow}(F(x))|^q f(x)dx
\]

\[
= \int_0^1 |F^{\leftarrow}(p) - \tilde{F}^{\leftarrow}(p)|^qdp
\]

\[\square\]

**Theorem 4.2.** Let \( F_{X|Z}(x) = P(X \leq x | Z = z) \) denote the cdf of \( X | \{Z = z\} \). Then \( g = F^{\leftarrow} \circ F_{X|Z} \) optimally transports \( X | \{Z = z\} \) to \( \tilde{X} \perp \!
\!
\perp Z \) for any cdf \( \tilde{F} \).

**Proof.** We apply Theorem 4.1 on the random variable \( X | \{Z = z\} \) and note that \( X | \{Z = z\} \) is independent of \( Z \). In particular, \( g(X | Z = z) \perp \!
\!
\perp Z \) for any choice of \( \tilde{F} \).

**Algorithm 2:** Algorithm for removing dependencies of \( Z \) from \( X \)

**Require:** \( X = [x_1, ..., x_n], Z = [z_1, ..., z_n], X | \{Z = z_j\} \sim F_{X|z_j}, \tilde{F} \) is a cdf for \( j = 1, ..., n \)

for \( j = 1, ..., n \) do

\( \tilde{x}_j = F^{\leftarrow}(F_{X|z_j}(x_j)) \)

end for

return \( \tilde{x} = [\tilde{x}_1, ..., \tilde{x}_n] \)

This procedure can also adapted for features sampled from discrete r.v’s, as shown in [14 Algorithm 1].
We would ideally pick $\tilde{F}$ such that it minimizes the transportation cost $g_c(X, \tilde{X}) = g_c(X, \tilde{F}^c(F_{X|z_j}(X)))$ across all cdfs $\tilde{F}$. However, in practice, the choice of $\tilde{F}$ does not matter much [14]. A standard choice for $\tilde{F}$ is $F_X$ so that we can recover the original quantiles of $X$, so we will assume this choice when applying this method to remove dependencies.

Furthermore, $F_{X|z_j}$ is not usually known and must be estimated from the data. This can be done by splitting $Z$ into $N$ quantiles and using the empirical cdf $P(X \leq x_j | Z \in z_j$’s quantile). The ability of this method to remove dependencies on $Z$ from $X$ relies significantly on the accuracy of this estimate.

We may iterate Algorithm 2 over each feature in $F \setminus Z$ to obtain pairwise independence between the transported variables $\tilde{X}_j$ and $Z$. It is also possible to iterate Algorithm 2 via chaining to achieve mutual independence between the transformed variables $X_j$ and $Z$ [14, 2.4]. However, this is computationally expensive, and pairwise independence should suffice for an accurate UMFI score, as will be explored further in Section 5. Step 2 of Algorithm 1 can therefore be implemented in the following way.

**Algorithm 3:** Algorithm for estimating $S^*$ via pairwise optimal transport

Require: $Z = \{z_1, ..., z_n\}, X_j = [x_{j1}, ..., x_{jn}]$ for $X_j$ in $F \setminus Z$

$S^* = \emptyset$

for $X_j$ in $F \setminus Z$

$\tilde{X}_j =$ output of Algorithm 2 with $X_j$ and $Z$

add $\tilde{X}_j$ to $S^*$

return $S^*$

In other words, we may estimate

$$S^* = \{F_{X|z_j}(X) : X \in F \setminus Z\} \subseteq F$$

### 4.2 Linear Regression

The most basic method for removing dependencies is linear regression. In fact, even though it is quite simple, it can be shown to be optimal with a few assumptions (Theorem 4.3). This preprocessing technique is implemented in the popular Python package fairlearn [17, 25].

To reiterate, removing dependencies requires methods to make a feature or set of features $S$ independent of a protected attribute $Z$, while keeping as much of the original information as possible. The overarching idea is that under the assumption that the residuals and the protected attribute are jointly Gaussian, we may show that the residuals can be utilized as a representation of $S$, which is independent of $Z$.

**Theorem 4.3.** Assuming no intercept term, if one specifies a simple linear regression model with

$$Y = \beta X + \epsilon$$

and $X$ and $\epsilon$ are joint normally distributed, then (1) $\epsilon \perp \perp X$ and (2) $\epsilon$ is correlated with $Y$ unless $Y$ can be completely
predicted from $X$.

**Proof.** (1) From the normal equations, the definition of covariance, and the fact that $\mathbb{E}[\epsilon] = 0$ we know:

$$\text{Cov}(X, \epsilon) = \mathbb{E}[X^T \epsilon] - \mathbb{E}[\epsilon] \mathbb{E}[X] = \mathbb{E}[X^T \epsilon] = \mathbb{E}[X^T (Y - X \beta)] = \mathbb{E}[X^T (Y - X (X^T X)^{-1} X^T Y)] = \mathbb{E}[X^T Y - X^T X (X^T X)^{-1} X^T Y] = \mathbb{E}[X^T Y - X^T Y] = 0,$$

since they are joint normal, $X \perp \perp \epsilon$. (2) From the definition of the response variable $Y$ and the distributive property for covariances we know $\text{Cov}(Y, \epsilon) = \text{Cov}(X \beta + \epsilon, \epsilon) = \beta \text{Cov}(X, \epsilon) + \text{Cov}(\epsilon, \epsilon) = \text{Var}(\epsilon)$.

Thus, given a protected attribute $Z$ and a feature set $F$, in step 2 the algorithm for UMFI (Algorithm 1), we estimate

$$S^* = \{\epsilon_i = X_i - \beta_{0,i} - \beta_{1,i} Z : X_i \in F \setminus Z\}.$$  

### 5 Experiments

In the following subsections, we will first compare the ability of linear regression and pairwise optimal transport to remove the information of a feature from data while distorting the original data as little as possible. In the second
subsection, we compare the feature importance scores of MCI and UMFI via several simulated datasets and one real dataset. We then experimentally test the computation time of each method as the number of features grow.

The data for the real world scenarios explored in sections 5.1.1, 5.2.4, and 5.2.5 is a breast cancer classification dataset (BRCA) [28]. The original data contains over 17,000 genes (explanatory variables) and 571 patients (observations), but a subset of the data was used instead for easier computation and result visualization. A set of 10 genes already experimentally associated with breast cancer were selected in addition to 40 random genes [27, 4, 4]. This data was used in several previous feature importance methods papers, including the original paper for MCI [27, 4, 4]. The data was downloaded from https://github.com/TAU-MLwell/Marginal- Contribution- Feature- Importance/ tree/main/BRCA_dataset. In sections 5.1 and 5.2.5 the experiments are run on a random selection of 15 of the 50 genes.

To implement UMFI paired with linear regression, we only remove dependencies when the regression slope coefficient perturbed features usually remains near 1. Linear regression does not distort the transformed features in most cases. The dependence between the original and other features with either linear regression or pairwise optimal transport (Figure 3). Not only do we require that the transformed features are independent of the feature of interest, but we also require that as much of the information present in the original data is also present in the transformed data. To measure the amount of distortion imposed on the original data, we measure the dependence between the original and perturbed data using the maximal information coefficient [29]. For each feature, the information from the current feature is removed from all other features with either linear regression or pairwise optimal transport (Figure 5). The protected attributes cannot be predicted successfully (OOB-accuracy for regression tasks and OOB classification accuracy for classification tasks) as the evaluation metric \(\nu\) [11]. We use the ranger R package to implement random forests with default hyperparameters and 100 for the number of trees [28]. In section 5.2.4, MCI is too computationally expensive to run for all 50 genes, so we assume 3-size-submodularity such that MCI can be computed exactly from random forest models only trained on all feature list subsets of size three or less [7, 4]. Code for these experiments can be found at https://github.com/joej1997/UMFI.

5.1 Comparing Linear Regression and Optimal Transport

5.1.1 Removing Dependencies

It is crucial for our linear regression and optimal transport methods to remove the information associated with the feature of interest, \(Z\), from the rest of the dataset. To measure the mutual information between \(Z\) and the transformed dataset \(S^*\), we assume that random forests are an optimal predictor. In practice, the mutual information between \(Z\) and \(S^*\) is difficult to calculate, but it is related to the optimal predictor of \(Z\) given \(S^*\). For example, if the mutual information between \(S^*\) and \(Z\) is 0, as is desired, then the optimal predictor of \(Z\) will have 0 accuracy given \(S^*\) [19]. If the opposite is true and the \(Z\) shares all of its information with \(S^*\), then an optimal predictor of should be able to perfectly predict \(Z\) from the given information in \(S^*\).

In the following experiments, we used a total of 15 features from the BRCA dataset. For each feature, we compute the mutual information between the current feature and the other 14 features. Each of these 14 features remain either untransformed, or the dependencies between the current feature and each of the other 14 features are removed via linear regression, or pairwise optimal transport. To measure mutual information, we train a random forests model on the 14 explanatory features, and we treat the current feature as the response. The mutual information is then computed as the OOB-\(R^2\) value coming from the random forest model. This process is run for each feature and each transformation method. The results are plotted in Figure 2. It is clear that the raw data (black line) shares considerable information across features. Most features can be predicted from the other untransformed features with an accuracy of \(R^2 > 0.2\) and many can even be predicted with accuracies over 0.3. Since the data has extremely nonlinear dependencies between features, simple linear regression is unable to remove all the mutual information between the protected attributes and the rest of the features. Indeed, the data certainly cannot be approximated with multivariate Gaussians. Conversely, pairwise optimal transport can successfully remove most of the mutual information present in the data. The protected attributes cannot be predicted successfully (OOB-\(R^2 = 0\)) using the other features after being transformed with pairwise optimal transport.

5.1.2 Distortion

Not only do we require that the transformed features are independent of the feature of interest, but we also require that as much of the information present in the original data is also present in the transformed data. To measure the amount of distortion imposed on the original data, we measure the dependence between the original and perturbed data using the maximal information coefficient [29]. For each feature, the information from the current feature is removed from all other features with either linear regression or pairwise optimal transport (Figure 5). Linear regression does not distort the transformed features in most cases. The dependence between the original and perturbed features usually remains near 1, though a few features drop their dependence to only 0.42 (Figure 5).
linear regression transformed these features with minimal distortion, these results are moot since linear regression failed to remove the original dependencies in a significant way, which was the main goal of the method (Figure 2).

Compared to linear regression, pairwise optimal transport has a much more sizable effect on the distorted features, though this may have been necessary to completely remove dependence. The dependence between original and perturbed features mostly ranges from 0.6-0.9, though some are as low as 0.37 (Figure 3).

5.2 Comparing MCI and UMFI

In the following subsections, we will compare MCI and UMFI with several simulation studies as well as on real data. Each of the simulation studies are repeated 100 times so that we can test the stability of each method. The data in all simulation studies contains one response, four explanatory features, and 500 randomly generated observations.

5.2.1 Correlated Interactions

Interacting features often are correlated [30], so testing if feature importance metrics work as desired in these settings is vital. Let $x_1 = A + B$, $x_2 = B + C$, $x_3 = D + E$, $x_4 = E + G$, where $A, B, C, D, E, G \sim \mathcal{N}(0, 1)$. The response variable, $Y$, is simulated as $Y = x_1 + x_2 + \text{sign}(x_1 \times x_2) + x_3 + x_4$. In this simulation, $x_1$ is correlated with $x_2$ and $x_3$ is correlated with $x_4$ in the same way. We would expect $x_1$ and $x_2$ to be more important than $x_3$ and $x_4$ because of the extra interaction term, $\text{sign}(x_1 \times x_2)$.

The results in Figure 4 clearly show that UMFI provides better estimations of feature importance compared to MCI when correlated interactions are present. The variability of all estimates are approximately the same across methods. However, MCI estimates that all features have the same feature importance scores, while both UMFI methods show significantly greater importance for $x_1$ and $x_2$ compared to $x_3$ and $x_4$.

5.2.2 Correlations

Marginal feature importance methods such as MCI and UMFI should not change the measured importance of features in the presence of correlated variables. To test this, we implement a simulation study similar to the ones found in [7][4]. Here, $x_1, x_2, x_4 \sim \mathcal{N}(0, 1)$, and $x_3$ is simulated as $x_1$ plus some noise, $\epsilon \sim \mathcal{N}(0, 0.2)$. The response $Y$ is set as $Y = x_1 + x_2$. Ideally, the addition of $x_3$ should not alter the importance of $x_1$, and $x_1$ should remain equally as important as $x_2$, since they have the same influence on the response $Y$.
Ultra Marginal Feature Importance

Figure 3: Cell \((i, j)\) indicates how similar the \(j^{th}\) variable is compared to its transformation via pairwise optimal transport or linear regression with respect to feature \(i\). This is measured with the maximal information coefficient, which is comparable to \(R^2\).

Figure 4: Feature importance scores for the Correlated Interaction simulation study. Feature importance scores are shown as a percentage of the total for each of \(x_1\) to \(x_4\). Results are shown for marginal contribution feature importance (MCI), ultra marginal feature importance with linear regression (UMFI-LI), and ultra marginal feature importance with pairwise optimal transport (UMFI-OT). Each box plot summarizes the results of the 100 replications of each simulation. The first and third quantiles (thin lines), the median (thick line), and outliers (points) of the 100 replications are shown.
Ultra Marginal Feature Importance

Figure 5: Feature importance scores for the Correlations simulation study. Feature importance scores are shown as a percentage of the total for each of x1 to x4. Results are shown for marginal contribution feature importance (MCI), ultra marginal feature importance with linear regression (UMFI-LI), and ultra marginal feature importance with pairwise optimal transport (UMFI-OT). Each box plot summarizes the results of the 100 replications of each simulation. The first and third quantiles (thin lines), the median (thick line), and outliers (points) of the 100 replications are shown.

The results shown in Figure 5 show that both MCI and UMFI work reasonably well. As with the previous simulation experiment, the variability is consistent across methods. As was desired, MCI and UMFI with linear regression show equal relative importance scores for x1 and x2. The importance given to x2 was slightly greater than x1 in the UMFI optimal transport scenario, but the difference is not significant. Interestingly, MCI assigns some importance to x4, which was independent of the response, while both UMFI methods assign importance scores close to 0. Because of this, we conclude that UMFI with linear regression performs the best in this simulated scenario.

5.2.3 Non-Linear Interactions

Interaction effects are common in many scientific disciplines where assessing feature importance is prevalent including hydrology [31, 32, 33], genomics [4, 34, 35], and finance [36, 37]. So, as was done in [7], we assess the ability of MCI and UMFI to detect non-linear interaction effects in the data.

This simulation study provides an xor-type causal relationship where individually, the explanatory features are unrelated with the response, but the response is influenced by the interaction of two features. Here, x1, x2, x3, x4 ∼ N(0, 1), ϵ ∼ Exp(1/√2), and Y = sign(x1 * x2) * ϵ [38]. Ideally, the results of a feature importance metric would conclude that x1 and x2 have equally high importance while x3 and x4 have no importance.

Figure 6 shows consistently good performance across all methods. Each method gave high relative importance scores to x1 and x2, while x3 and x4 received scores near 0. This is perfect as the response was only a function of x1 and x2, while it was independent of x3 and x4. The only difference across methods is that the variability of estimates was slightly greater when using UMFI with optimal transport compared with the other methods.

5.2.4 BRCA

We ran MCI, UMFI with linear regression, and UMFI with pairwise optimal transport on the breast cancer classification dataset BRCA [26]. The results for this are shown in Figure 7. All methods agree that BCL11A is the most important gene for determining breast cancer classification, which is aligned with previous studies showing that BCL11A may cause an aggressive form of breast cancer [27, 39]. Further, SLC22A5 ranks in the top three genes for all methods, and TEX14 is always the least important BRCA associated gene. Among the non-BRCA associated genes CST9L is highly ranked in all methods, so this is a good candidate for further research. While there are clearly important similarities in the results of all methods, the glaring difference is the number of features given 0 importance. While MCI gives non-zero importance to all 40 features, 14 features are given 0 importance by UMFI with linear regression, and 10
Ultra Marginal Feature Importance

Figure 6: Feature importance scores for the Non-Linear Interactions simulation study. Feature importance scores are shown as a percentage of the total for each of x1 to x4. Results are shown for marginal contribution feature importance (MCI), ultra marginal feature importance with linear regression (UMFI-LI), and ultra marginal feature importance with pairwise optimal transport (UMFI-OT). Each box plot summarizes the results of the 100 replications of each simulation. The first and third quantiles (thin lines), the median (thick line), and outliers (points) of the 100 replications are shown.

features are given 0 importance by UMFI with pairwise optimal transport. None of the features given 0 importance showed any association with breast cancer in previous studies. It is likely unrealistic to assume that all 40 randomly selected genes cause or are associated with breast cancer, so in this respect, UMFI can perform better than MCI. A similar phenomenon occurred in the Correlation simulation experiment, where a feature completely unrelated to the response is given non-zero importance by MCI. Even though theoretically, UMFI should always dominate MCI ($U_\nu(f) \geq I_\nu(f)$), we hypothesize that in practice, UMFI can give lower importance due to the instability of random forests when trained on only a few features as is done when computing MCI. If random forests are trained on one or two features, then the correlation between trees may increase dramatically, therefore giving a poor representation of an idealized evaluation function, $\nu$. Because the maximizing subset in (2.1) may be very small or even empty, then MCI is more susceptible to this instability compared to UMFI, which uses $|F| - 1$ modified features for predictions.

5.2.5 Computational Complexity

To compute exactly, MCI must train and evaluate a model for each element of the power set of the feature set. If the feature set has $p$ features, then the size of the power set is $2^p$, so MCI requires $O(2^p)$ model trainings for exact computation. On the other hand, for UMFI, we may immediately estimate the maximizing set of features by removing the dependencies of $f$ from the feature set $F$. Our experimental results indicate that it suffices to remove dependencies of $f$ from each feature in $F \setminus \{f\}$, however, optimal estimates may impose significantly more computational cost. To compute the ultra marginal feature importance of a single feature, the evaluation function $\nu$ must be computed twice, so UMFI requires $O(p)$ model trainings to compute the feature importance for all $p$ features. Since pairwise optimal transport is much more expensive compared to linear regression, we use UMFI with pairwise optimal transport in these experiments to compare MCI with the worst case of UMFI.

To confirm the above statements and to show that the computation time for removing dependencies does not dominate the extra model trainings required for MCI, we ran a simple experiment. For a range of dataset sizes, randomly chosen from the BRCA data, we evaluate the computation time of calculating the feature importance scores of all features using MCI and UMFI. We ran this for dataset sizes ranging from 5 — 15 features and the results are shown in Figure 8. MCI is indeed significantly more computationally expensive compared to UMFI. When looking more closely at the computational time for UMFI, it is clear that it is super-linear due to the extra step of removing dependencies with optimal transport, but even with 50 features, the computation time is less than 30 seconds.
Figure 7: Feature importance scores provided by (a) MCI, (b) UMFI with linear regression, and (c) UMFI with pairwise optimal transport, for each gene in the BRCA dataset. Genes colored in blue are known to be associated with breast cancer while genes colored in grey are randomly selected genes not associated with breast cancer.
In this study, we built upon the framework laid out by marginal contribution feature importance (MCI) and introduced a new feature importance metric called ultra marginal feature importance (UMFI). We showed that UMFI can be estimated directly for a feature $f$ by finding the largest information subset of the feature set $F$ that is independent of $f$. This signified the importance of removing dependencies for our method, which we explored using optimal transport and linear regression. After several experiments comparing optimal transport and linear regression, it can be concluded that linear regression works optimally on simulated data and when the data is jointly Gaussian. However on real data, such as the BRCA dataset, pairwise optimal transport can find independent representations of the data, while linear regression fails. When comparing UMFI and MCI, not only does UMFI satisfy the key axioms used to define MCI, but it also has the ability to obtain faster and more accurate estimates of marginal feature importance on real and simulated data. There were three shortcomings of MCI that we found could be resolved with UMFI. First, computing the exact MCI value requires $O(2^p)$ model trainings, which is computationally preventative for many scenarios such as genome-wide association studies, which may have $p > 100,000$ features. Second, MCI cannot detect correlated interactions in some circumstances, but it was showed in a simulation study that UMFI could detect correlated interactions. Third, MCI may overestimate the importance of features that are not related to the response.

Throughout the work on this paper, several shortcomings appeared. Most importantly, we only considered two simple methods for removing dependencies, namely linear regression and pairwise optimal transport. Other methods certainly exist in the literature, including optimal transport with chaining [14], neural networks [18, 19], or principal inertial components [16]. Though our two methods performed fairly well on the real and simulated datasets we discussed in Section 5, the limitations of both optimal transport and linear regression appeared when we tested the methods on a hydrology dataset with more shared information compared to BRCA [40]. In this case, linear regression and pairwise optimal transport failed to find representations of the data that were independent of the protected attribute. However, neural nets or principal inertial components certainly could have given better results. Also, despite requiring significantly more computational cost, optimal transport with chaining should give better estimates for $S^*$. In future work, we would like to test how well other methods such as neural networks pair with UMFI while further testing on a wider variety of random variable types such as binary, categorical, and ordinal features. Further, we would like to explore how well dependence can be removed and UMFI can be estimated on real data as the number of increases to sizes much larger than 50.

To reiterate, UMFI is a powerful tool to find feature importance if explaining the data is the primary goal. We emphasise that UMFI is just a framework. A variety of other methods can be used to estimate the evaluation function including, but not limited to, XGBoost, neural networks, or Gaussian processes. Further, preprocessing techniques for dependence removal is still an active area of research, so as new methods are discovered, they can be applied to UMFI instead of...
Ultra Marginal Feature Importance

linear regression or optimal transport. We hope that UMFI will be a useful tool in a variety of disciplines including bioinformatics, ecology, earth sciences, and health science for discovering scientific processes and relationships hidden within data.

Acknowledgments

We thank Dr. Elina Robeva for her support and encouragement during this process. We thank all of the authors of the papers we cited, especially Dr. Chandra Nair for his help with concepts in information theory.
