**On Learning the Invisible in Photoacoustic Tomography with Flat Directionally Sensitive Detector**

**Bolin Pan** and **Marta M. Betcke**

**Abstract.** In photoacoustic tomography (PAT) with flat sensor, we routinely encounter two types of limited data. The first is due to using a finite sensor and is especially perceptible if the region of interest is large relatively to the sensor or located farther away from the sensor. In this paper, we focus on the second type caused by a varying sensitivity of the sensor to the incoming wavefront direction which can be modelled as binary i.e. by a cone of sensitivity. Such visibility conditions result, in Fourier domain, in a restriction of both the image and the data to a bowtie, akin to the one corresponding to the range of the forward operator. The visible ranges, in image and data domains, are related by the wavefront direction mapping. We adapt the wedge restricted Curvelet decomposition, we previously proposed for the representation of the full PAT data, to separate the visible and invisible wavefronts in the image. We optimally combine fast approximate operators with tailored deep neural network architectures into efficient learned reconstruction methods which perform reconstruction of the visible coefficients and the invisible coefficients are learned from a training set of similar data.

**Key words.** learned image reconstruction, compressed sensing, Curvelet transform, photoacoustic tomography, fast Fourier methods, limited view

1. **Introduction.** Photoacoustic Tomography (PAT) is a hybrid imaging modality that can deliver high resolution *in-vivo* images of absorbed optical energy upon illumination with laser-generated near-infra-red light pulse [59, 11, 44, 57, 65, 60]. PAT harnesses the photoacoustic effect to encode optical contrast onto broadband ultrasonic waves thereby circumventing the depth and spatial resolution limitations of purely optical imaging techniques.

If the data is measured over a surface surrounding the region of interest for long enough time and using omnidirectional sensors, the reconstruction can be obtained via *time reversal* which amounts to a single solve of a wave equation; see section 2 for details. In practice, the limited-view problems are introduced due to spatially and/or directionally restricted sampling of the ultrasound (US) waves. An example of the former is a finite size linear/planar sensor placed on one side of the domain, and of the latter most US sensors’ incapability of recording wavefronts impinging on the detector at angles beyond $\pm \theta_{\text{max}}$, $\theta_{\text{max}} < \pi/2$. Another type of limited-view problems result from restricting the length of the recorded time series, a necessity arising in a case of trapping sound speeds. As in this work we focus on constant speed of sound, we do not consider this last type of limited-view problems.

For limited-data problems due to sparse sampling rather than limited-view, compressed sensing (CS) approaches that iteratively minimise a penalty function combining an explicit model of US propagation with constraints on the image as regularisation [38, 10, 8, 33, 39, 15, 16].
52, 45, 28, 30, 26, 27, 29, 47] have proven to provide significantly better reconstructions than time reversal and more general Newton series based iterative methods which lack inherent regularisation. A shared drawback of all these methods is high computational complexity of iterating with the forward and adjoint/inverse operators. This shortcoming has been addressed by two step methods which reconstruct complete data first and then obtain the image through single time reversal [33, 13, 45], which however usually sacrifice some reconstruction quality for efficiency.

For the considered limited-view problems the situation is more dire. Time reversal and Newton series methods as expected only reconstruct the visible singularities producing images with characteristic limited-view artefacts and lack noise suppression properties of CS methods [63]. Performance of compressed sensing depends on the choice of the prior, e.g. while total variation (TV) yields overall better reconstructions than Curvelet sparsity (reasons for which are discussed in subsection 6.3), even for TV the directions of singularities missing from the data result in inherent blur in the reconstructed images.

A decade after the breakthrough in Deep Neural Networks, Deep Learning (DL) techniques are ubiquitous in tomographic imaging [41, 40, 34, 1, 66, 2, 9]. In comparison to CS, the learned approaches i) need fewer applications of the forward/adjoint operator which leads to more efficient reconstruction algorithms, ii) have the ability to extract prior information about the image from a training set of similar images which makes them particularly suitable for e.g. medical image reconstruction where patient studies fit such scenario. DL approaches to PAT image reconstruction mainly fall in one of the two categories: i) learned post-processing of a simple reconstruction such as e.g. pseudo-inverse, ii) learned iterative reconstruction (also referred to as model based learning).

The learned post-processing usually employs a network with many layers and learnable parameters capable of encoding complicated image priors. The learned post-processing of the universal back-projection [61] was studied in [6, 7, 5, 51, 50, 43], of the first iteration of an averaged time reversal in [53] and of time reversal in [32]. All but the last work use standard U-Net architecture, while the last uses a dense U-Net (an U-Net with dense blocks and skip connections). The main advantage of learned post-processing is that an initial simple reconstruction can be decoupled from the iterative training process. This obviously limits the impact of the physical model on the reconstruction procedure and hence makes the process less robust and more dependent on the training set used.

Learned iterative reconstruction approaches are based on unrolling of iterative solvers and parametrising the proximal map with neural networks, usually much smaller than those used in learned post-processing, e.g. [54, 17, 16, 14, 64]. Due to repeated application of the forward and adjoint/approximate inverse operators on the training set, learned iterative reconstruction methods for 3D PAT suffer from unreasonable training times. To tackle this, a greedy training for learned gradient schemes for 3D PAT was suggested in [37]. The same authors later considered use of efficient Fourier domain approximate forward model to accelerate the training process [35], which is also the direction we take in this work.

Other proposed approaches include learned pre-processing of the data prior to reconstruction, fully learned methods completely bypassing the physics of the model, and methods that aim to learn some representation of the regulariser for use in variational framework, we refer to [36] for a review of such approaches specific to PAT.
1.1. Related work. In series of papers Frikel and Quinto [47, 26, 29, 27, 48] characterised the visibility of singularities in X-ray tomography and in [63, 30] in PAT with finite omnidirectional flat sensor ($\theta_{\text{max}} = \pi/2$). The limitations of CS approaches with Curvelet sparsity regularisation were discussed in [26, 27] in the context of X-ray tomography.

Motivated by these works, a number of authors considered implications of the visible and invisible singularities for learning methods in limited-angle tomography in X-ray and in general [19, 18, 3]. In [3] the authors proposed an approach which uses the canonical relation between the singularities of the Radon transform, in image and data domains, to inpaint the singularities extracted from the data using network proposed in [4] into the reconstructed image. In [18] the authors reinterpret the unrolled ISTA iteration as CNN layers which coefficients and structure are inferred from the convolutional properties of Fourier integral operators and pseudo-differential operators and apply it to limited-angle X-ray tomography. The present work is closest in spirit to the approach proposed in [19] for the limited-angle X-ray tomography which promotes the idea to separate the visible part of the image, which can be stably reconstructed in Shearlets frame using CS approach, from the invisible part of the image which needs to be learned. The main benefits of such approach are i) a clear separation between what is reconstructed from the measured data and the prior that is learned from the training set and ii) decoupling of the reconstruction of the visible which requires iterating with the forward/adjoint operator from learning the invisible which does not, as the invisible is contained in the null space of the forward operator. A similar idea was proposed from an algebraic perspective as null space learning in [49].

1.2. Motivation. In this work we focus on the limited-view problem due to varying sensitivity of the sensor to the direction of the wavefront impinging on the detector. The directional sensitivity can be modelled as binary with a maximal impingement angle $\pm \theta_{\text{max}}$, $\theta_{\text{max}} < \pi/2$, for the wavefronts to be registered, resulting in a cone of sensitivity around the direction normal to the sensor. We observe this problem shares many similarities with the limited-angle for parallel X-ray transform, in particular the decomposition into visible/invisible singularities in the Fourier domain which can be strictly realised using directional frames like Curvelets or Shearlets. This decomposition into visible and invisible singularities for limited-angle parallel X-ray geometry underpins the result in [27] on visible singularities only recovery via compressed sensing in Curvelets or Shearlets frames.

Based on this result, the authors of [19] proposed to reconstruct the visible and learn the invisible in Shearlet frame for the limited-angle parallel X-ray tomography. These results along with the above observation of similarities between the limited-angle parallel X-ray CT and limited view (due to sensitivity angle) in flat sensor PAT motivate our work.

Using the wavefront mapping (WfM) [45], we obtain the correspondence between the visible and invisible wavefront directions in PAT image and PAT data. This allows us the observation that the limited sensitivity angle restricts the data range in a way that enables use of efficient Fourier domain forward/adjoint and pseudoinverse operators derived in subsection 3.1.

We adapt the wedge restricted Curvelet transform, proposed in [45] for PAT data representation, to the representation of the visible/invisible components of the PAT image (initial pressure, $p_0$), and recover the visible singularities via CS in a wedge restricted Curvelet frame.
with the data fidelity term using the aforementioned limited angle PAT Fourier operators. The visible component of the PAT image is then represented by its Coronae coefficients, a minimal representation which perfectly matches the split into the visible/invisible and the multiscale structure induced by the Curvelet frame, introduced in subsection 5.2.2. These visible Coronae coefficients are fed into a Coronae-Net, a tailored U-Net inspired architecture, designed and trained to fill in the invisible component of the PAT image given the visible component.

2. Photoacoustic Tomography. With several assumptions on the tissue properties [58], the photoacoustic forward problem can be modelled as an initial value problem for the free space wave equation

\[
\left( \frac{1}{c^2(x, t)} \frac{\partial^2}{\partial t^2} - \nabla^2 \right) p(t, x) = 0, \quad (t, x) \in (0, T) \times \mathbb{R}^d,
\]

(A)

\[
p(0, x) = p_0(x),
\]

\[
p_t(0, x) = 0,
\]

where \( p(t, x) \in C^\infty((0, T) \times \mathbb{R}^d) \) is a time dependent acoustic pressure recorded for a finite time \( T \), \( p_0(x) \in C^\infty_0(\mathbb{R}^d) \) is its initial value, and \( c(x) \in C^\infty(\mathbb{R}^d) \) is the speed of sound in the tissue.

The photoacoustic inverse problem recovers the initial pressure \( p_0(x) \) in the region of interest \( \Omega \) on which \( p_0(x) \) is compactly supported, from time dependent measurements \( g(t, x_S) = \omega(t)p(t, x_S), \quad (t, x_S) \in (0, T) \times S \) at a set of locations \( x_S \in S \subset \mathbb{R}^d \), e.g. the boundary of \( \Omega \), where \( \omega \in C^\infty_0(0, T) \) is a temporal smooth cut-off function. It amounts to a solution of the following initial value problem for the wave equation with constraints on the surface [25]

\[
\Box^2 p(t, x) = 0, \quad (t, x) \in (0, T) \times \mathbb{R}^d,
\]

(TR)

\[
p(0, x) = 0, \quad p_t(0, x) = 0,
\]

\[
p(t, x) = g(T - t, x_S), \quad (t, x_S) \in (0, T) \times S,
\]

also referred to as a time reversal. For non-trapping smooth \( c(x) \), in 3D, the solution of (TR) is the solution of the PAT inverse problems if \( T \) is chosen large enough so that \( g(t, x) = 0 \) for all \( x \in \Omega, \ t \geq T \) and the wave has left the domain \( \Omega \). Assuming that the measurement surface \( S \) surrounds the region of interest \( \Omega \) containing the support of initial pressure \( p_0 \), the wave equation (TR) has a unique solution.

When no complete data is available (meaning that some singularities have not been observed at all as opposed to the case where partial energy has been recorded, see e.g. [56]), \( p_0 \) is usually recovered in a variational framework, including some additional penalty functional corresponding to prior knowledge about the solution. Iterative methods for solution of such problems require application of the adjoint operator which amounts to the solution of the

This manuscript is for review purposes only.
following initial value problem with time varying mass source [10]

\[
\Box^2 q(t, x) = \begin{cases}
\frac{\partial}{\partial t} g(T - t, x_S), & (t, x_S) \in (0, T) \times S \\
0 & \text{everywhere else}
\end{cases}
\]

(A*)

\[
q(0, x) = 0,
\]

\[
q_t(0, x) = 0,
\]

evaluated at \( T \), \( q(T, x) \).

3. Fourier domain formulation of PAT. The operators defined in this section map be-
tween Fourier transforms of the initial pressure \( p_0 \) and the data \( g \). When using Fourier domain
PAT operators in conjunction with Curvelet frame (which is also defined and computed via
the Fourier transform), all the computations can be carried out directly in Fourier domain
without need to compute intermediate Fourier transforms.

3.1. Forward, adjoint and inverse PAT operators in Fourier domain. Assuming half
space symmetry as per line sensor geometry in 2D (plane sensor in 3D) with a constant speed
of sound \( c(x) = c \), the solution of the wave equation (A) in Fourier domain can be explicitly
written as [23]

\[
\hat{p}(t, k) = \cos(c|k|t) \hat{p}_0(k),
\]

where \( \hat{u} \) denotes the Fourier transform of \( u \) in some or all variables and \( k \in \mathbb{R}^d \) is the Fourier
domain wave vector. Using (3.1), we can obtain the following forward mapping between
the initial pressure \( p_0(x_\perp, x_S) \), \( (x_\perp, x_S) \in \mathbb{R} \times \mathbb{R}^{d-1} \) and the PAT data \( g(ct, x_S) \), \( (ct, x_S) \in \mathbb{R} \times \mathbb{R}^{d-1} \) with \( g(ct, x_S) = p(ct, x_S) \) in Fourier domain [23, 42, 62, 13]

\[
\hat{g}(\omega/c, k_S) = \frac{\omega/c}{\sqrt{(\omega/c)^2 - |k_S|^2}} \hat{p}_0 \left( \sqrt{(\omega/c)^2 - |k_S|^2}, k_S \right),
\]

where \( \cdot_\perp \) denotes the ambient space coordinate perpendicular to the sensor, time \( t \) and its
frequency \( \omega \) are understood as non-negative quantities, with symmetries defining the functions
on their negatives. In particular, formula (3.1) has an implicit assumption of even symmetry
of \( p_0(x_\perp, x_S) \), \( g(ct, x_S) \) in \( \mathbb{R}^d \) w.r.t. \( x_\perp = 0 \), \( ct = 0 \), respectively,

\[
\hat{p}_0(-k_\perp, k_S) = \hat{p}_0(k_\perp, k_S),
\]

\[
\hat{g}(-\omega/c, k_S) = \hat{g}(\omega/c, k_S).
\]

The constant speed of sound \( c \) is used to normalise time/frequencies, the non-normalised
formulation contains additional factor \( 1/c \) on the right hand side of (A) [45]. For the right hand
side of equation (A) to be real and bounded, the expression under the square root should be
bounded away from zero for all non-zero wave vectors i.e. \( \mathcal{R}_A = \{ (\omega/c, k_S) \in \mathbb{R}^d : |k_S| < \omega/c \} \)
\( \cup 0 \), resulting in a bow-tie shaped range of photoacoustic operator in the sound-speed nor-
malised Fourier space, see Figure 2 (b). We note that (A) turned around underlies the
inverse transform (which is stable) [42], but as forward transform the factor blows up and
regularisation is required [35].
As already alluded, the inverse PAT Fourier operator follows immediately from $(\hat{A})$,

$$(\hat{A}^{-1}) \quad \hat{p}_0(\mathbf{k}_\perp,\mathbf{k}_S) = \frac{|\mathbf{k}_\perp|}{|\mathbf{k}|} \hat{g}(|\mathbf{k}|,\mathbf{k}_S),$$

with the change of variables induced by the dispersion relation in the wave equation $(\omega/c)^2 = |\mathbf{k}|^2 = |\mathbf{k}_S|^2 + |\mathbf{k}_\perp|^2$,

$$(3.3) \quad \mathbf{k} = (\mathbf{k}_\perp,\mathbf{k}_S) \leftarrow \left( \sqrt{(\omega/c)^2 - |\mathbf{k}_S|^2}, \mathbf{k}_S \right),$$

$$(\omega/c,\mathbf{k}_S) \leftarrow \left( |\mathbf{k}| = \sqrt{|\mathbf{k}_\perp|^2 + |\mathbf{k}_S|^2}, \mathbf{k}_S \right).$$

Using the definition the adjoint, the adjoint PAT Fourier operator was derived in the Appendix A

$$(\hat{A}^*) \quad \hat{p}_0(\mathbf{k}_\perp,\mathbf{k}_S) = \hat{g}(|\mathbf{k}|,\mathbf{k}_S).$$

We note that both inverse $(\hat{A}^{-1})$ and adjoint $(\hat{A}^*)$ operators only differ by the scaling factor present in the inverse and absent from the adjoint, while the underlying change of variables is the same.

3.2. Wavefront direction mapping. The wave front mapping (WfM) was derived in [45] observing that the change of coordinates (3.3) defines a one-to-one map between the frequency vectors $\mathbf{k} = (\mathbf{k}_\perp,\mathbf{k}_S) \in \mathbb{R}^d$ and $(\omega/c,\mathbf{k}_S) \in \mathcal{R}_A$. This mapping is illustrated below. Figure 1 (a) shows the wavefronts and the corresponding wavefront vectors in the ambient space $\tilde{\theta} = (-\cos \theta, \sin \theta)$ on the left and in the data space $\tilde{\beta} = (\cos \beta, -\sin \beta)$ on the right. Note, that these wavefront vectors have the same direction as their frequency domain counterparts $\mathbf{k}_\tilde{\theta}, \mathbf{k}_\tilde{\beta}$ which are depicted in Figure 1 (b). The even symmetry (3.2) is inherited by the map (3.3).

With the notation in Figure 1, we deduce the map between the wavefront vector angles $\tilde{\theta}$ and $\tilde{\beta}$ (which are the same in space and frequency domains)

$$(3.4) \quad \tan \tilde{\beta} = \frac{k_\beta}{k_{\omega/c}} = \frac{-k_\beta}{|k_\tilde{\theta}|} = \sqrt{|k_\perp|^2 + |k_\tilde{\theta}|^2} = \sin(-\tilde{\theta}).$$

Using the relation with wavefront vector angles $\tilde{\theta} = \pi - \theta$, $\tilde{\beta} = 2\pi - \beta$ and basic trigonometric identities, from equation (3.4), we obtain the corresponding map between $\theta$ and $\beta$

(WfM) \quad \beta = \arctan (\sin \theta),

where $\theta \in (-\pi/2, \pi/2)$ and $\beta \in (-\pi/4, \pi/4)$ for the un-mirrored initial pressure. The derivation was presented in $\mathbb{R}^d$, $d = 2$ for simplicity, $d = 3$ follows analogously by treating both detector coordinates the same, see also [45].
Figure 1: (a) Wavefront direction mapping between the ambient space $\theta$ (left), and the data space, $\beta$ (right) on an example of a 2D spherical wave. $-\theta$ and $-\beta$ are the angles that the wavefronts (in blue) make with the sensor plane. (b) The Fourier domain counterpart, the wavefront vector mapping between $k\theta$ (left), and $k\beta$ (right).

### 3.3. Limited-angle PAT Fourier operators.

According to the wavefront mapping ($WfM$) we have

$$\tan \beta_{\text{max}} = \sin \theta_{\text{max}},$$

which yields the correspondence between the visible ambient space wavefronts $[-\theta_{\text{max}}, \theta_{\text{max}}]$, $\theta_{\text{max}} < \pi/2$ and the visible data space wavefronts $\beta \in [-\beta_{\text{max}}, \beta_{\text{max}}]$, $\beta_{\text{max}} < \pi/4$. Thus we only need to restrict the range of $\theta$ in equation (\hat{A}) to formulate the limited-angle PAT Fourier forward operator

$$\hat{A}_\angle \hat{g}(\omega/c, k_S) = \frac{\omega/c}{\sqrt{(\omega/c)^2 - |k_S|^2}} \hat{p}_0 \left( \sqrt{(\omega/c)^2 - |k_S|^2}, k_S \right), \quad |k_S| \leq \sin(\theta_{\text{max}})|k|.$$ 

($\hat{A}_\angle$) maps from the domain $\mathcal{D}_\angle = \left\{ (k_{\perp}, k_S) \in \mathbb{R}^d : |k_S| \leq \sin(\theta_{\text{max}})|k| \right\}$, $\sin \theta_{\text{max}} < 1$ onto the narrowed bow-tie shaped range $\mathcal{R}_\angle = \left\{ (\omega/c, k_S) \in \mathbb{R}^d : |k_S| \leq (\omega/c) \tan \beta_{\text{max}} \right\}$, $\tan \beta_{\text{max}} < 1$.

A Fourier domain illustration of the visibility in ambient space for $\theta_{\text{max}} = \pi/3$ is shown in Figure 2 (a), and the corresponding narrowing down of the bow-tie shaped range in Fourier transformed data space is highlighted with the red cut-off line in Figure 2 (b). With this restriction $|\theta| \leq \theta_{\text{max}} < \pi/2$, the denominator of $\hat{A}_\angle$ is bounded away from 0,

$$\omega/c^2 - |k_S|^2 \geq (1 - \tan^2 \beta_{\text{max}})(\omega/c)^2 = (\omega/c)^2 \cos^2 \theta_{\text{max}} > 0,$$

and the limited-angle PAT Fourier forward operator can be stably evaluated. We note, that our restriction is equivalent to an upper bound on the factor (suggested as regularisation in [35])

$$\frac{\omega/c}{\sqrt{(\omega/c)^2 - |k_S|^2}} = \frac{|k|}{|k_{\perp}|} = \frac{1}{\cos \theta} \leq D,$$

This manuscript is for review purposes only.
Figure 2: Contour plot of $k_\perp = \text{const}$ over the bow-tie shaped (a) domain of the limited angle PAT Fourier forward operator, $\theta_{\text{max}} = \pi/3$, (b) range of the PAT Fourier forward operator with the further narrowed range of the limited angle PAT Fourier forward operator highlighted with the red dashed line.

with the choice of $D = (\cos \theta_{\text{max}})^{-1}$.

We can now analogously define the limited-angle PAT Fourier inverse operator, $\mathcal{R}_A \rightarrow D_A$

\[
(\hat{A}_\perp^{-1}) \quad \hat{p}_0(k_\perp, k_S) = \frac{|k_\perp|}{|k|} \hat{g}(|k|, k_S), \quad |k_S| \leq \sin(\theta_{\text{max}})|k|,
\]

and the limited-angle PAT Fourier adjoint operator, $\mathcal{R}_A^* \rightarrow D_A^*$

\[
(\hat{A}_\perp^*) \quad \hat{p}_0(k_\perp, k_S) = \hat{g}(|k|, k_S), \quad |k_S| \leq \sin(\theta_{\text{max}})|k|.
\]

We note, that in practice the functions $p_0, g$ are discretized on an a grid in $\mathbb{R}^d$ and discrete fast Fourier transforms along with interpolation are used for evaluation of the operators. We use the same notation for the continuous and discrete operators, as their meaning is clear from the context.

Finally, we consider a non-variational approach based on the Neumann-series [56, 46] which is known to effectively restore partially visible singularities which arise in limited-view problems. The $k$-th iterate in the Neumann series approach with the limited-angle PAT Fourier operators is obtained as

\[
(iN) \quad p^{k}_{iN} = \sum_{i=0}^{k} K^i \hat{A}_\perp^{-1} g_\perp, \quad \text{with} \quad K = I - \hat{A}_\perp^{-1} \hat{A}_\perp,
\]

where $I$ is the identity operator over $\mathbb{R}^d$ and $g_\perp = \hat{A}_\perp p_0$ is the limited-angle data (here

This manuscript is for review purposes only.
noiseless). The reformulation of \((iN)\) leads to an iterative image reconstruction scheme

\[
p_{k}^{l+1} = \sum_{i=0}^{k+1} K^{-1} \hat{A}^{-1} g_{\ell} = K \sum_{i=0}^{k} K^{-1} \hat{A}^{-1} g_{\ell} + \hat{A}^{-1} g_{\ell} = K p_{k}^{l} + \hat{A}^{-1} g_{\ell}
\]

\[
= (I - \hat{A}^{-1} \hat{A}) p_{k}^{l} + \hat{A}^{-1} g_{\ell}
\]

\[
= p_{k}^{l} - \hat{A}^{-1} (\hat{A} p_{k}^{l} - g_{\ell}).
\]

The effect of the limited-angle PAT Fourier forward model in data domain is demonstrated in Figure 3 on the 4-disk phantom with line sensor on top. The disks are placed inside the north sector of the square domain so to eliminate any effect of the finite sensor. Comparing the approximated full-angle data \((\theta_{\text{max}} \approx \pi/2)\) in (b) with the limited-angle data \((\theta_{\text{max}} = \pi/4)\)\(^1\) in (c), we observe Gibbs like phenomena, i.e. the aliasing is more perceptible for a larger range of visible angles leading to a larger sup norm. On the first sight, there is an apparent similarity between (d) the limited-angle inversion \(p_{0}^{\text{Linear}} = \hat{A}^{-1} g_{\ell}\) and (e) the limited-angle adjoint \(p_{0}^{\text{Adj}} = \hat{A}^{*} g_{\ell}\), however we point out a noticeable difference in contrast due to the frequency dependent factor \(|k|/|k_{\ell}|\) present in the inverse but not in the adjoint. We observe that the Neumann series reconstruction \(iN(g_{\ell})\) (f) is almost the same as the direct linear inversion \(p_{0}^{\text{Linear}}\) (d). This is a consequence of the half space geometry with planar / line sensor, where each wavefront is measured exactly once, i.e. we measure the wavefront travelling towards the detector and the wavefront in the opposite direction is accounted for by assuming the mirror symmetry of the data w.r.t. the detector hyperplane. Thus the limited angle (nor actually the limited sensor) does not result in any partially measured singularities (all or nothing) and hence no improvement can be expected by the iterative Neumann series approach.

4.1. Curvelets. Curvelet transform [20] is a multiscale pyramid with many directions and positions at each scale. Figure 4 (a) shows the Curvelet induced tiling of the Fourier domain in 2D, with Curvelet window functions supported near a trapezoidal wedge with the orientation \(\theta_{l}, \theta_{l} \in [-\pi, \pi)\) and the scale \(j\). The corresponding Curvelet envelope function in spatial domain is aligned along a ridge of length \(2^{-j/2}\) and width \(2^{-j}\). The wedges/envelopes become finer with increasing scale which lends the Curvelet frame the ability to resolve singularities along curves.

We introduce the Curvelet transform following the continuous presentation in [20]. For each scale \(j\), orientation \(\theta_{l} = 2\pi/l : 2^{-|j|/2} \cdot l, l \in \mathbb{Z}^{d-1}\) such that \(\theta_{l} \in [-\pi, \pi)^{d-1}\) \((L \cdot 2^{j/2})\) is the number of angles at the second coarsest scale \(j = j_{0} + 1, j_{0}\) even), and translation \(a \in \mathbb{Z}^{d}\), the Curvelet coefficients of \(u : \mathbb{R}^{d} \rightarrow \mathbb{R}\), are computed as

\[
(C) \quad C_{j,l}(a) = \int_{\mathbb{R}^{d}} \hat{u}(k) \hat{U}_{j,\theta_{l}}(k)e^{i\mathbf{a}^{(j,l)} \mathbf{k}}dk,
\]

which is a projection of the Fourier transform \(\hat{u}(k)\) on the corresponding frame element function \(\hat{U}_{j,\theta_{l}}(k)\exp(-ik \cdot x_{l}^{(j,l)})\) with \(\hat{U}_{j,\theta_{l}}(k)\) a trapezoidal frequency window with scale \(j\) and

\(^1\)In real data acquisition scenarios with Fabry Perr\'ot sensor, \(\theta_{\text{max}}\) is empirically found to be \(\approx \pi/4\).
orientation $\theta_l$, and a spatial domain centre at $x_{a}^{(l)}$ corresponding to the sequence of translation parameters $a = (a_1, 2^{-j}, ..., a_d, 2^{-j/2})$, $a_1, ..., a_d \in \mathbb{Z}^d$. Note that the coarse scale Curvelets are isotropic Wavelets corresponding to translations of an isotropic low pass window $\tilde{U}_0(k)$. The window functions at all scales and orientations form a smooth partition of unity on the relevant part of $\mathbb{R}^d$. For real function $u$, we use the symmetric version of the Curvelet transform corresponding to the Hermitian symmetry of the wedges $\theta_l$ and $\theta_l + \pi$ in the frequency domain. There are two different ways to evaluate the integral (C) efficiently. In this paper, we use the implementation via wrapping i.e. the digital coronisation with shears introduced in [20]. This fast digital Curvelet transform is a numerical isometry. We refer to [20] for further details and to Curvelab package\footnote{http://www.curvelet.org/software.html} for the 2D and 3D implementation.

4.2. Fully wedge restricted Curvelets. Let $k_0 \in \mathbb{R}^d$ be Curvelet wavefront vector corresponding to the orientation $\theta = [\theta, \theta^d]^{d-1}$ and $\hat{k}^i \in \mathbb{R}^d$ a unit vector along the $i$th coordinate direction. In $2D$ $\theta = \angle(k^1, k_0) \in [-\pi, \pi)$ is just a single angle, in $3D$ we have 2 angles and in $\mathbb{R}^d, d - 1$ angles. The wedge restricted Curvelet transform\footnote{https://github.com/BolinPan/Wedge_Restricted_Curvelet} [45] amounts to computing the directional Curvelet coefficients (C) only for a wedge-shaped subset of angles $\theta_l \in [\theta_b, \theta_b^d] \cup [-\pi, \pi]^{d-1}$. The symmetric wedge restricted Curvelet transform restricts the Curvelet

---

This manuscript is for review purposes only.
orienations to the symmetric double wedge (bow-tie) \( \theta_l \in W := [-\theta^w, \theta^w] \cup [-\theta^w + \pi, \theta^w + \pi] \) with \( \theta^w \in (0, \pi/2)^{d-1} \) as illustrated in Figure 4 (b) for 2D, where the gray region corresponds to the Curvelet with orientations inside the bow-tie range.

The drawback of the original formulation of the wedge restricted Curvelet transform are the isotropic Wavelet window functions at the coarse scale inherited from the original Curvelet transform which result in non-directional coarse scale coefficients. To overcome this shortcoming, we enforce the split into in and out of wedge frequencies also at the coarse scale \( j_0 \) by applying a binary bow-tie filter to the coarse scale in Fourier domain, and henceforth we refer to this construction as a **fully wedge restricted Curvelet transform**. Formally we can write the fully wedge restricted Curvelet transform \( \tilde{\Psi} : \mathbb{R}^n \rightarrow \mathbb{R}^{\tilde{N}} \) as a composition of the standard Curvelet transform \( \Psi : \mathbb{R}^n \rightarrow \mathbb{R}^N \) and a projection operator \( P_W : \mathbb{R}^N \rightarrow \mathbb{R}^{\tilde{N}} \),

\[
P_W = P_W \Psi
\]

where the angles \( \theta_{j,l} \) are the discrete wedge orientations (essentially corresponding to the wedge centres). We note the fully wedge restricted Curvelet transform is an isometry when defined on the restriction to the range of \( P_W \) i.e. \( \tilde{\Psi} : \mathbb{R}^n |_{\text{range}(P_W)} \rightarrow \mathbb{R}^{\tilde{N}} \), where \( \text{range}(P_W) \) corresponds to the set \( W \) in the Fourier domain. Figure 4 (b,c) illustrate the difference between the Fourier domain ranges of the wedge restricted and fully wedge restricted Curvelet transforms in 2D.

Figure 4: (a) An example of a 2D frequency domain Curvelet tiling using 3 scales. The highlighted wedge, magnified view in top right, corresponds to the frequency window near which the Curvelet \( \tilde{U}_{j,\theta_l} \) at the scale \( j \) with orientation \( \theta_l \) is supported. The orientation of the envelope of the corresponding Curvelet function in the spatial domain is shown in bottom right corner. Induced (b) wedge restricted (c) fully wedge restricted Curvelet transforms for \( \theta_{\text{max}} = \pi/4 \). The respective bow-tie shaped ranges are coloured gray.

### 4.3. Fully wedge restricted Curvelet representation of initial pressure

Curvelets provide an almost optimally sparse representation if the function \( u : \mathbb{R}^d \rightarrow \mathbb{R} \) is smooth away from

---

https://github.com/BolinPan/CoronaeNet

This manuscript is for review purposes only.
from (piecewise) $C^2$ singularities [22, 55, 24]. More precisely, the error of the best $s$-term approximation, $u_s$, (corresponding to taking the $s$ largest in magnitude coefficients) in Curvelet frame decays as [22]

$$||u - u_s||_2^2 \leq O((\log s)^3 \cdot s^{-2}).$$

Furthermore, Curvelets have been shown to sparsely propagate through the wave equation [21] essentially being translated along the trajectories of the Hamiltonian flow with initial conditions corresponding to the spatial domain centre and the direction of the Curvelet. For constant speed of sound, this implies that the angle $\theta$ at which the Curvelet impinges on the detector is the same as the Curvelet orientation in the decomposition of the initial pressure $p_0$. A direct consequence of the restriction of the angle $|\theta| \leq \theta_{\text{max}}$ is the restriction to the visible initial pressure $p_0$, which corresponds to symmetric fully wedge restricted Curvelet transform with directions $\theta_l \in W_{\text{max}}^\theta, W_{\text{max}}^\theta := [-\theta_{\text{max}}, \theta_{\text{max}}] \cup [-\theta_{\text{max}} + \pi, \theta_{\text{max}} + \pi]$ with $\theta_{\text{max}} \in (0, \pi/2)^{d-1}$. On the other hand, the restriction of the impingement angle, $|\theta| \leq \theta_{\text{max}}$, translates via (WfM) into the restriction of the angle $\beta, |\beta| \leq \arctan(\sin \theta_{\text{max}})$, implying narrowing of the bow-tie shaped range of the PAT forward operator to $W_{\text{max}}^\beta := [-\beta_{\text{max}}, \beta_{\text{max}}] \cup [-\beta_{\text{max}} + \pi, \beta_{\text{max}} + \pi]$ with $\beta_{\text{max}} = \arctan(\sin \theta_{\text{max}}) \in (0, \pi/4)^{d-1}$.

We now reinterpret (C) to obtain the symmetric fully wedge restricted Curvelet transform for representation of the visible initial pressure

$$(\text{FWRC}) \quad \hat{C}_{j,l}(a_\perp, a_S) = \int_{\mathbb{R}^d} \hat{u}(k_\perp, k_S) \hat{U}_{j,\theta_{\text{max}}, l}(k_\perp, k_S) e^{i(x_\perp(k_\perp, k_S))} dk_\perp dk_S, \quad \theta_{j,l} \in W_{\text{max}},$$

with the following notation

$$(k_\perp, k_S) \text{ ambient/image domain frequency } k = (k_\perp, k_S):$$

$\theta_{j,l}$ a discrete direction of a trapezoidal frequency window $\hat{U}_{j,\theta_{\text{max}}, l}(k_\perp, k_S)$. The tiling is computed using standard Curvelet transform on a cuboid domain, followed by the projection $P_W$ on the bow-tie shaped set $W_{\text{max}}$; We remark, that efficient implementation would bypass the computation of the wedges outside $W_{\text{max}}$, but it would require modifications to the Curvelet Toolbox functions.

$W_{\text{max}}$ the restriction of $\theta_{j,l}$ to those in the bow-tie $W_{\text{max}} := [-\theta_{\text{max}}, \theta_{\text{max}}] \cup [-\theta_{\text{max}} + \pi, \theta_{\text{max}} + \pi]$ with $\theta_{\text{max}} \in (0, \pi/2)^{d-1}$ effects the projection on the visible range of initial pressure in Fourier domain;

$$(a_\perp, a_S) \text{ the grid of spatial translations: } a_S \text{ parallel to the detector } S, a_\perp \text{ perpendicular to } S$$

(note that Curvelet transform via wrapping uses one grid per each quadrant at each scale, a.k.a. $x_\perp^Q = (2^{-j}a_\perp^Q, 2^{-j/2}a_S^Q)$, $Q = \{N, W, S, E\}$).

We note that in practice, the function $p_0 : \mathbb{R}^d \to \mathbb{R}$ is discretised on an $n$ point grid in $\mathbb{R}^d$, yielding a vector $p_0 \in \mathbb{R}^n$, and we apply the symmetric discrete Curvelet transform $\hat{\Psi} : \mathbb{R}^n \to \mathbb{R}^N$. The discrete counterparts of the wedge restricted $\hat{\Psi}$ and fully wedge restricted $\hat{\Psi}$ transforms follow analogously.

We compare the standard Curvelet transform $\hat{\Psi}$, wedge restricted Curvelet transform $\hat{\Psi}$ with fully wedge restricted Curvelet transform $\hat{\Psi}$ for $\theta_{\text{max}} = \pi/4$ on the 4-disk phantom (shown in Figure 3 (a)). We use 3 scales and 32 angles (at the 2nd coarsest level) for the standard Curvelet transform, yielding wedge restricted transforms with 16 angles (at the 2nd coarsest

This manuscript is for review purposes only.
level). Both the wedge restricted Curvelet transform and the fully wedge restricted Curvelet transforms exclude the wedges out of the bow-tie range $W_{\text{max}}$ at the higher $j > j_0$ scales; see Figure 5 (b,c). The standard Curvelet transform and the wedge restricted Curvelet transform have the same coarse scale coefficients while the fully wedge restricted Curvelet transform enforces the split of the coarse scale into visible $\theta_{j,l} \in W_{\text{max}}$ and invisible $\theta_{j,l} \notin W_{\text{max}}$ to obtain the visible initial pressure only; see Figure 5 (d-f).

The projections effected by all three Curvelet transforms are shown in Figure 6. Figure 6 (c,f) illustrates that the projection on the range of fully wedge restricted Curvelet transform corresponds to the visible initial pressure.

Figure 5: 4-disk Phantom - Curvelet coefficients of 4-disk phantom ($\theta_{\text{max}} = \pi/4$ for wedge restriction): (a) standard, (b) wedge restricted, (c) fully wedge restricted Curvelet transform coefficient magnitudes; (d-f) the corresponding coarse scale coefficients.

5. Reconstructing the visible and learning the invisible. The fully wedge restricted Curvelet transform introduced in subsection 4.3 allows us to decompose the initial pressure $p_0 \in \mathbb{R}^n$ into Curvelet coefficients that belong to either the visible $f^{\text{vis}} \in \mathbb{R}^\mathcal{N}$ or the invisible $f^{\text{inv}} \in \mathbb{R}^{\mathcal{N}}$ initial pressure (in the sense that the other coefficients are set to 0)

\[
\begin{align*}
  f^{\text{vis}} &= \tilde{\Psi} p_0, \\
  f^{\text{inv}} &= \tilde{\Psi}^\perp p_0.
\end{align*}
\]

(VID)

Given the limited-view data $g_\angle \in \mathbb{R}^m$ contaminated with additive white noise, the visible initial pressure $p_0$ can be reconstructed by reconstructing the visible coefficients of $p_0$ in the fully wedge restricted Curvelet frame. The latter is a standard compressed sensing $\ell_2 - \ell_1$ minimisation problem with the $\ell_2$ data fidelity term involving the aforementioned limited-angle PAT Fourier forward operator. As the invisible coefficients are out of range of the

This manuscript is for review purposes only.
Figure 6: 4-disk Phantom - Visualisation of projection effected by the different types of Curvelet transform ($\theta_{\text{max}} = \pi/4$ for wedge restriction): projection on the range of (a) standard $\Psi$, (b) wedge restricted $\tilde{\Psi}$, (c) fully wedge restricted $\hat{\Psi}$; (d-f) projection on corresponding range complements in $\mathbb{R}^d$.

5.1. Reconstructing the Visible. In this step, we recover the visible part of initial pressure $p_0 \in \mathbb{R}^n$ from noisy measurement $g_{\angle} \in \mathbb{R}^m$ in a fully wedge restricted Curvelet frame. To this end we solve

\[
\tilde{f}^{\text{vis}} \in \arg \min_f \frac{1}{2} \| \hat{A}_\angle \Psi^\dagger f - \hat{g}_{\angle} \|_2^2 + \tau \| \Lambda f \|_1,
\]

where $\hat{A}_\angle : \mathcal{D}_{\hat{A}} \to \mathcal{R}_{\hat{A}}$ is the discrete limited-angle PAT Fourier forward operator, $\Psi^\dagger : \mathbb{R}^N \to \mathbb{R}^n$ is the left inverse (and an adjoint) of the fully wedge restricted Curvelet transform $\hat{\Psi}$, $f$ are the coefficients of $p_0$ in $\hat{\Psi}$, $\tilde{f}^{\text{vis}}$ are the reconstructed visible Curvelet coefficients, and the regularisation parameter $\tau$ is made scale dependent by multiplication with $\Lambda = \text{diag}(2^{j-2})$, where $j \geq j_0$ is the vectors containing the scales of the basis elements $\hat{\Psi}$. We propose to solve (VR) using FISTA [12] with a pre-computed Lipschitz constant $L = \| \Psi \hat{A}_\angle^\dagger \hat{A}_\angle \Psi^\dagger \|_2$.

5.2. Learning the invisible. Armed with the visible reconstruction $f^{\text{vis}}$, we now learn the invisible coefficients by a tailored U-Net. As the invisible coefficients are out of range of the forward operator $i.e. f^{\text{inv}} \in \ker(\hat{A}_\angle)$ [27], $f^{\text{inv}}$ can not be reconstructed from $g_{\angle}$. Instead we can recover the invisible coefficients using a trained CNN. We refer to such two step method as reconstructing the visible and learning the invisible.

5 As already mentioned in section 3 all the computations can be executed directly in Fourier domain. For simplicity we use the same notation for transforms ($\Psi$, $\tilde{\Psi}$, $\hat{\Psi}$), which act on the Fourier transform $\hat{p}_0$ for these that act on $p_0$ itself.
forward operator, there is no need/benefit to include the forward and adjoint operators into the network. Our network is based on U-Net architecture, which we refer to as Coronae-Net (CorNet) is depicted in Figure 10. We use the Coronae Decomposition in lieu of downsampling and the Coronae Reconstruction in lieu of upsampling. The input of CorNet are visible Coronae coefficients which are generated from the reconstructed visible Curvelet coefficients. The visible Coronae coefficients are mapped to a latent representation via a series of convolutions, non-linearities and high/low-pass filters on the down branch of the CorNet. The correlations between the visible and invisible part of the image are encoded in this latent representation during training and allow prediction of the invisible part of the image. The decoder branch of the CorNet, decodes and upsamples both visible and invisible Coronae coefficients to the highest scale output.

5.2.1. Coronae Decomposition and Reconstruction. The Coronae decomposition is motivated from the Curvelet transform, where the high-pass and low-pass filter bank is applied to effect the scale (frequency band) decomposition. Coronae decomposition is computed in Fourier domain but the Coronae coefficients at each scale are images obtain with inverse scale restricted Fourier transform. We make use of the same smooth partition of unity filters as used in Curvelet Toolbox. We henceforth denote the filter pair at scale \( j \) with \( L_j \) the low-pass filter and \( H_j = \sqrt{1 - (L_j)^2} \) the high-pass filter. For each scale \( j \), the image \( p_j \) has the size

\[
\left( \frac{n_j}{3 \cdot 2^j - 1} + 2 \cdot \left\lfloor \frac{n_j}{3 \cdot 2^j - 1} \right\rfloor + 1 \right) \times \left( \frac{m_j}{3 \cdot 2^j - 1} + 2 \cdot \left\lfloor \frac{m_j}{3 \cdot 2^j - 1} \right\rfloor + 1 \right),
\]

where \( j_0 \leq j < j_0 + J \) and \( n_j \times m_j \) is the image size of \( p_{j_0+J} \). \( H_j(p_j) \) returns the high-pass component with the same size as \( p_j \) and \( L_j(p_j) \) the low-pass component with the size of \( p_{j-1} \); see Figure 8 for visualisation of the effect of 1-level of Coronae decomposition of the 4-disk phantom. The Fourier domain computations involved in Coronae decomposition are schematically shown in Figure 7 (where for visualisation purposes the overlapping smooth partition of unity filters are replaced with discontinuous non-overlapping partition of unity by characteristic function of the pass-through). The signal can be recovered by the Coronae reconstruction. The Coronae reconstruction upsamples the low-pass component via zero-padding and sums up the padded low-pass component with the corresponding high-pass component in Fourier domain to recover the original signal (denoted with \( \oplus \)). Based on this 1-level Coronae decomposition effected by the pair \( (L_j, H_j) \) we can form a filter bank via recursion for the decomposition

\[
((L_{j-1}, H_{j-1}), H_{j-1}(L_{j}), H_j), \quad j = j_0 + J, \ldots, j_0 + 1,
\]

and for the reconstruction

\[
(L_{j-1} \oplus H_{j-1}) \oplus H_j, \quad j = j_0 + 1, \ldots, j_0 + J,
\]

Figure 7 (right) displays a 3 scale filter bank where the red and green arrows indicate the Coronae decompositions and reconstructions, respectively.

---

\footnote{Such filters require appropriate wrapping of the low pass component \( L_j(p_j) \) before Fourier inversion at scale \( j - 1 \).}

Figure 8: 1-level Coronae decomposition of a 4-disk phantom: (a) $p_0$, (b) high-pass component $H(p_0)$, and (c) low-pass component $L(p_0)$.

5.2.2. Rationale for Using Coronae Coefficients as Network Input. There are two disadvantages to usage of individual Curvelets as a network input. Firstly, to preserve the locality of the CNN convolutions (with kernels with localized support, frequently 2 or 3 pixels), they need to be applied in image domain. In the most straightforward realisation, this would required computing an image domain representation of each individual Curvelet $\hat{\Psi}^\dagger(C_j(a))$, $j \geq j_0$ (see Figure 9 (a-c)) which, even when using scale appropriate image sizes, would result in a prohibitive number of image inputs. A better alternative is to use the images of each individual trapezoidal wedge window (as are used for displaying the Curvelet coefficients c.f. Figure 5). However, these are still numerous due to parabolic scaling induced doubling every second scale. Furthermore, their size varies even within the scale which would require additional processing e.g. zero-padding. We are however, interested in the split into visible and invisible parts rather than in individual Curvelet coefficients. This is most economically represented by the Coronae decomposition applied to the visible/invisible parts of the image (see Figure 9 (d,e) which results in two channel input (visible and invisible channel)). Secondly, it is apparent from Figure 9 that Coronae decomposition is a more economic and a higher level feature representation, as it is not reliant on a superposition for final representation unlike Curvelet decomposition. Thus we can reasonably expect it will be easier to learn.
The relation of the Coronae and Curvelet decompositions can be formally stated in Fourier domain as

\[ \hat{Q}_j(k_j) = \sum_l \int_{\mathbb{R}^d} C_{j,l}(a_{j,l}) e^{-i x_{a_{j,l}} \cdot k_j} \, da_{j,l}, \]  

where \( k_j \) is the frequency domain vector restricted to scales \( j \geq j_0 \) and \( x_{a_{j,l}} \) are the Curvelet centers at scale \( j \) and angle \( \theta_{j,l} \). In particular, when using implementation via wrapping we have one grid per quadrant \( x_{a_{j,l}} = x_{a_{j,0}} \). The coarse scale Coronae and Curvelet coefficients coincide.

In what follows Coronae transform will be applied to the visible and invisible parts of the image which corresponds to restricting the sum in (QC) to the visible wedge \( W_{\text{max}} \) or its complement for invisible coefficients. The implementation bypasses the computation of the Curvelet transform. After Fourier domain application of the bow-tie shaped filter to extract the visible \( k \in W_{\text{max}} \) and its complement the invisible \( k \not\in W_{\text{max}} \), we use the filters bank define in subsection 5.2.1 to obtain the Coronae decomposition \( Q \) of each visible/invisible component directly. Figure 9 (d-f) shows 2-level Coronae decomposition coefficients of the 4-disk phantom.

![Figure 9](image)

Figure 9: 4-disk Phantom - Spatial representation of visible Curvelet coefficients (a-c) and of visible Coronae coefficients (d-f) at scales \{C, SF, F\} \((\theta_{\text{max}} = \pi/4)\).

### 5.2.3. Coronae-Net

We propose a following Coronae-Net (CorNet) which we construct with a depth matching the number of scales of the Curvelet decomposition. The input at each scale \( j \) consists of 2 channels: the first channel is the Coronae coefficient \( Q_j(p^{\text{vis}}) \) of

Note that the overlapping smooth partition of unity filters yield larger \( k_j \) than the 0-1 non-overlapping filters.

---

*This manuscript is for review purposes only.*
the visible and the second channel will be used to predict the unknown Coronae coefficient $Q_j(p^{\text{inv}})$ of the invisible. At the input stage the latter could be initialised with 0 but in practice adding random white noise in training is preferable. In the encoder branch, scale by scale the convolutions and nonlinearities extract and correlate the features of the visible and invisible Coronae coefficients to effect the prediction of the invisible Coronae coefficients. The Coronae decomposition is used to pass the low-pass components downward and high-pass components directly to the decoder via the skip connection. On the up-branch the visible and predicted invisible features are decoded via a symmetric cascade of convolutions and nonlinearities. The Coronae reconstruction is used assemble the high-pass components passed through the skip connection with the low-pass components obtained from the deeper layer. We highlight the asymmetry in the CorNet input and output, while we input the Coronae coefficients scale-wise, the output Coronae coefficients are upsampled (via 0-padding) and returned at the finest scale. Furthermore, the output is multi-headed, as popular in multi-task learning framework, which allows us to assign different weights to coefficients at different scales (and possibly even to visible and invisible channels).

Although the output contains both visible and invisible, the loss function is only applied to the invisible Coronae coefficients and can be written as

$$(PL) \quad \mathcal{L}(\mathcal{N}\mathcal{N}_{\text{Cor}}(Q^{P_{\text{vis}}}), \tilde{Q}^{P_{\text{inv}}}) = \sum_j \left( \alpha_j \cdot \text{MSE}\left(\mathcal{N}\mathcal{N}_{\text{Cor}}(Q^{P_{\text{vis}}}_j), \tilde{Q}^{P_{\text{inv}}}_j\right) \right), \quad j \in \{j_0, \ldots, j_0 + J\},$$

where the perfect visible Coronae coefficients (original size) $Q^{P_{\text{vis}}}_j$ are the input to the CorNet, $\mathcal{N}\mathcal{N}_{\text{Cor}}$, $\tilde{Q}^{P_{\text{inv}}}_j$ are the upsampled to the finest-scale perfect/reference invisible Coronae coefficients, and $\alpha_j$ are some fixed scale dependent weights. The total loss ($PL$) is summed over the training set of in/output pairs of $Q^{P_{\text{vis}}}$ and $\tilde{Q}^{P_{\text{inv}}}$.

Figure 10: Coronae-Net - Architecture here shown with 3 scales for learning the invisible Coronae coefficients in 2D. The Coronae decomposition and reconstruction are used as down-sampling and upsampling in the network, respectively.

Recall the invisible Curvelet coefficients are in the kernel of the limited-angle PAT Fourier

This manuscript is for review purposes only.
forward operator. The same holds for invisible Corone coefficients, c.f. subsection 5.2.2 thus learning the invisible with CorNet from perfect visible coefficients also follows a null space learning paradigm as the scheme presented in [49], but our chosen representation is essentially optimal for both the image representation and the PAT forward operator.

\[ Q^{\text{Fvis}} + P_{\text{ker}(\hat{A}_\angle)}\mathcal{N}\mathcal{N}_{\text{Cor}}(Q^{\text{Fvis}}), \]

where \( P_{\text{ker}(\hat{A}_\angle)} \) the projection on \( \text{ker}(\hat{A}_\angle) \), extracts the invisible output channel.

5.2.4. ResCoronae-Net. The main limitation of the perfect/null space learning is the assumption of availability of perfect visible coefficients. In realistic scenarios the reconstructed visible Corone coefficients \( Q^{\text{vis}} \) will suffer from artefacts introduced by the reconstruction procedure. In our case, the Fourier operators contain an error due to interpolation between image and data domain grids. Therefore, we propose a residual version of the CoronaeNet, \( \text{ResCoronae-Net} \) (ResCorNet), to learn an update to both visible and invisible Corone coefficients. We use the same 0 or random noise initialisation for the invisible coefficients as for CorNet, thus the residual connection has no effect for invisible coefficients. We note that we need to upsample our inputs to the finest scale to match the output size before the residual connections (the diagram of ResCoronae-Net can be found in supplementary material Figure SM1). The loss function used for the residual learning penalises errors in both visible and invisible Corone coefficients (IPL)

\[ \mathcal{L}(\mathcal{N}\mathcal{N}_{\text{ResCor}}(Q^{\text{Ivis}}), \tilde{Q}^{\text{Pall}}) = \sum_j (\alpha_j \cdot \text{MSE}(\mathcal{N}\mathcal{N}_{\text{ResCor}}(Q^{\text{Ivis}})_j, \tilde{Q}^{\text{Pall}})_j), \quad j \in \{j_0, \ldots, j_0 + J\}, \]

where the reconstructed imperfect visible Corone coefficients (original size) \( Q^{\text{Ivis}}_j \) are the input to the ResCorNet, \( \mathcal{N}\mathcal{N}_{\text{ResCor}}, \tilde{Q}^{\text{Pall}}_j \) are the upsampled to the finest-scale perfect/reference visible and invisible Corone coefficients, and \( \alpha_j \) some fixed scale dependent weights. Again, the total loss (IPL) is summed over the training set of in/output pairs of \( Q^{\text{Ivis}} \) and \( \tilde{Q}^{\text{Pall}} \).

6. Synthetic Data. In this section, we evaluate the performance of our proposed reconstruction scheme and compare it with various other reconstruction methods. We focus on two learning scenarios: 1) Perfect Learning, learns the invisible Corone coefficients from the given perfect visible Corone coefficients via CorNet with loss function (PL); 2) Imperfect Learning, learns the update of the visible and the invisible Corone coefficients, from the imperfect visible Corone coefficients, constructed from the solution of (VR), via ResCorNet with loss function (IPL).

6.1. Experimental Setup. We evaluate our proposed method on an ellipse data set. The data consists of 3000 synthetic images of superposition of random ellipses (number, location, orientation and contrast) with resolution of \( n_{x_\perp} \times n_S = 192 \times 192 \) and a uniform voxel size \( h_x = 10 \mu m \). The locations of the ellipses are randomly chosen within the upper half of the image to reduce (while not eliminate completely) the limited sensor effect. The individual images are normalised between 0 and 1 (see Figure 11 (a) for a representative image sample from the ellipse data set).
We assume homogeneous speed of sound $c = 1500\text{m/s}$. The pressure time series is recorded every $h_t = 66.67\text{ns}$ by a line sensor with sensitivity angle $\theta_{\text{max}} = \pi/4$ on top of the domain with image matching resolution i.e. $h_x = 10\mu$m, which we can interpret as number of time-steps $\times$ number of sensors shaped PAT data volume, $272 \times 192$.

We use the fully wedge restricted Curvelet transform with 3 scales and 16 angles in the wedge $W_{\text{max}}$ (at the 2nd coarse scale) for the sparse representation of initial pressure $p_0$. The parameters of the transform determine the structure of the networks such as depth (equal to the number of scales, here 3), and the input/output sizes.

We trained all the networks presented in this section in the same manner to make a fair comparison. 2400 images are used for training, 300 images for validation and 300 for testing. We chose Adam as the optimizer with Xavier initialisation [31] and batch size of 2. We trained all networks for 200 epochs with 20 epochs early stopping to avoid over-fitting. The initial learning rate is set to $1 \cdot 10^{-3}$ with a cosine decay. Each network is trained in PyTorch on a single Tesla K40c GPU.

6.2. Perfect Learning. We start with an idealised experiment where we learn the invisible Coronae coefficients from the perfect visible Coronae coefficients. The perfect visible/invisible image components and Coronae coefficients of each image $p_0$ in the data set are computed directly via projections $p_0^{\text{vis}} = \bar{\Psi}^j \bar{\Psi} p_0$, $p_0^{\text{inv}} = p_0 - \bar{\Psi}^j \bar{\Psi} p_0$ or Coronae decomposition or $p_0$.

The variation in magnitudes and sizes of Coronae coefficients across scales, suggests use of larger weights for higher scales. The choice of $\alpha_T = 2$, $\alpha_S = 2$ and $\alpha_C = 1$ in (PL) lead to best network performance. We quantitatively compare the results of CorNet with standard variational approaches and U-Net based learned post-processing on the ellipse test data, in terms of MSE, PSNR and SSIM averaged over the test set.

We compare our results to two reference learned post-processing methods, based on U-Net architecture, trained to remove limited-view artefacts. $\mathcal{N}U_{\text{Net}}(p_0^{\text{vis}})$ takes as an input the perfect visible component $p_0^{\text{vis}}$ and is trained on $(p_0^{\text{vis}}, p_0)$ pairs with MSE loss. $\mathcal{N}U_{\text{Net}}(Q_j^{\text{vis}})$ takes as an input the upsampled to the finest scale (via zero-padding in Fourier domain) perfect visible Coronae coefficients $\hat{Q}_j^{\text{vis}}$ (a.k.a. multichannel input at highest scale only, one channel per scale) and is trained on $(\hat{Q}_j^{\text{vis}}, \hat{Q}_j^{\text{all}})$ pairs with MSE loss. The diagrams of the reference U-Nets can be found in supplementary material.

A visualisation of the reconstruction quality for one of the test images is given in Figure 11. The first row of Figure 11 displays the initial pressure $p_0$ along with its decomposition into perfect visible $p_0^{\text{vis}}$ and perfect invisible $p_0^{\text{inv}}$ parts. The second row of Figure 11 illustrates
ON LEARNING THE INVISIBLE IN LIMITED ANGLE PAT

Figure 11: Ellipses - Visualisation of performance of perfect learning on one test image ($\theta_{\text{max}} = \pi/4$): (a) the initial pressure $p_0$, (b) the perfect visible component of $p_0$, (c) the perfect invisible component of $p_0$, (d-f) different learned reconstructions.

the learned reconstructions (pixel values clipped to [0,1] range). Although all three methods perform very well, the zoomed-in insets in Figure 11 reveal our proposed scheme yields superior reconstruction in terms of invisible boundary (green inset), ellipse shapes and faint contrasts (red inset). On average, $\mathcal{N}^\text{Cor}(Q_{\text{vis}}^I)$ achieves lowest MSE, highest PSNR and highest SSIM in Table 1 which is consistent with better, in eye ball metric, reconstructions produced by the CorNet\textsuperscript{8}. However, we observe all methods in (d-f) fail to recover the faint ellipse on top of even fainter large ellipse and overlapping with ellipses with higher contrasts (highlighted in green inset). The low contrast boundary of the faint ellipse is difficult to pick up for the networks. We encountered a similar scenario in Figure 8, where the boundary of the faint blue ellipse is almost invisible in the high-pass component $H(p_0)$ while the boundaries of the ellipses with higher contrast are still perceptible.

6.3. Imperfect Learning. Next, we consider the more practical scenario of correcting the visible and learning the invisible Coronae coefficients on the ellipse data set from PAT data with additive white noise with standard deviation $\sigma = 2.5 \cdot 10^{-4}$. We reconstruct the visible Curvelet coefficients $\tilde{f}_{\text{vis}}$ solving (VR) with regularisation parameter $\tau = 2.5 \cdot 10^{-4}$ and 50 iterations. This scenario employs ResCorNet with the scale dependent loss weights $\alpha_F = 2$, $\alpha_{SF} = 2$ and $\alpha_C = 1$ in (IPL). Again we compare the results obtained with ResCorNet against and residual variants of U-Net learned post-processing methods on the test subset of ellipse data.

We compare our results to five reference methods. $p_0^{\text{Linear}} = \hat{A}^{-1}_\perp g_\perp$: linear inversion from

\textsuperscript{8}The invisible Coronae coefficients $\tilde{Q}_j^{I_{\text{inv}}}$ learned using CorNet can be found in supplementary material.

This manuscript is for review purposes only.
noisy limited-view data \( g \cdot p_0^{\text{vis}} \): recovery of the visible part of \( p_0 \) in fully wedge restricted Curvelet frame via (VR). \( p_0^{\text{TV}} \): total variation regularised solution with non-negativity constraint [8]. And two learned post-processing methods based on ResU-Net architecture trained to remove artefacts due to limited angle and errors in the visible Coronae coefficients. \( \mathcal{N} \mathcal{R}_{\text{ResU-Net}}(p_0^{\text{vis}}) \): takes as an input the imperfect visible coefficients \( p_0^{\text{vis}} \) and is trained on \((p_0^{\text{vis}}, p_0)\) pairs with MSE loss. \( \mathcal{N} \mathcal{R}_{\text{ResU-Net}}(\hat{Q}_j^{\text{vis}}) \): takes as an input the (upsampled to the finest scale via zero-padding in Fourier domain) imperfect visible Coronae coefficients \( \hat{Q}_j^{\text{vis}} \) and is trained on \((\hat{Q}_j^{\text{vis}}, \hat{Q}_j^{\text{P}})\) pairs with MSE loss. The diagrams of the reference ResU-Nets can be found in supplementary material.

The image quality measures averaged over the 300 test images are listed in Table 2, specifically MSE, PSNR and SSIM with respect to the provided ground-truth images. The reconstruction quality is illustrated on an example from the test set in Figure 12. Despite \( p_0^{\text{TV}} \) achieving highest SSIM, the reconstructed boundaries of the ellipses highlighted in the white inset in Figure 12 (c) are incomplete (total variation apparently fails to completely recover the invisible boundaries) and considerably worse than for the learning based reconstructions (d-f). We note that the linear reconstruction \( p_0^{\text{Linear}} \) in Figure 12 (a) and \( p_0^{\text{vis}} \) in Figure 12 (b) look similar with slight difference in contrast. The linear inversion results in slightly less clear ellipse boundaries and noisier image than the non-linear \( \ell_1 \) reconstruction; see blue inset in Figure 12 (a,b). We recall, that the linear inversion here is able to recover the visible component due to limited-angle (and even limited sensor) completely, thus any
difference should be due to higher robustness of the non-linear reconstruction to noise. This is consistent with the latter’s lower MSE, higher PSNR and higher SSIM compared to the linear inversion. The second row in Figure 12 (clipped to range [0,1]) shows the results of post-processing with ResU-Nets and ResCorNet, respectively. Although the ResU-Net based methods in Figure 12 (d,e) estimate the invisible boundaries reasonably well they exhibit some high frequency noise. Upon closer inspection (white and yellow insets Figure 12) and quantitative analysis in Table 2, our proposed ResCorNet seems to strike the best balance between the recovery of invisible boundaries while preserving the piece-wise constant interior of the ellipses. Similarly as in the perfect learning scenario, all three methods in (d-f) fail to recover the faint green framed ellipse.

The timing and resources are listed in Table 3 (Note $p_{0\ell_1}^{I_{\text{vis}}}$ and $p_{0TV+}^{I_{\text{vis}}}$ are evaluated using Matlab Parallel Computing Toolbox\(^9\)). Clearly $\mathcal{NN}_{\text{ResU-Net}}(p_{0}^{I_{\text{vis}}})$ is fastest to train and execute, while $\mathcal{NN}_{\text{ResCor}}(Q_{j}^{I_{\text{vis}}})$ requires longest training time. The main reason is due to ResCorNet’s larger number of trainable parameters: 1) the preceding convolutions at each scale are paramount to extract the features from the scale-wise Coronae coefficients input; 2) the Coronae coefficients sizes are determined by the partition of unity filters underpinning Curvelet decomposition, which result in larger sizes of layer inputs at each but the finest scale than those obtained from max-pooling. It is noteworthy that at prediction stage, the approaches learning the Coronae coefficients $\mathcal{NN}_{\text{ResU-Net}}(Q_{j}^{I_{\text{vis}}})$ and $\mathcal{NN}_{\text{ResCor}}(Q_{j}^{I_{\text{vis}}})$ only

---

have a slight overhead compared to $\mathcal{NN}_{\text{ResU-Net}}(P_0^{(\text{vis})})$, and are much faster than the variational reconstruction approaches.

### 6.4. Generalisation.

We now consider the generalisation properties of (Res)CorNet. To this end we chose an 4-disk phantom depicted in Figure 13. The 4-disk phantom is not in the ellipse data set, while disk being a special case of an ellipse, it has similar features such as convexity and boundaries of $C^2$ type. In this experiment, the visible Curvelet coefficients are obtained solving $\text{(VR)}$ with $\tau = 2.5 \cdot 10^{-4}$ and 50 iterations. Again the white noise with standard deviation $\sigma = 2.5 \cdot 10^{-4}$ is added to the corresponding limited-view data with $\theta_{\text{max}} = \pi/4$. We apply the ResCorNet trained on the ellipse data set to the 4-disk phantom. This scenario corresponds to training on a complicated data set and generalising our model to a less complex image with some shared and some unseen characteristics. We note that the training set contains many ellipses at least partially outside the north sector of the domain (inside which the limited sensor has no bearing on the reconstruction) while our 4-disk phantom lies strictly inside. The main limitation of the ResU-Net based reconstructions in Figure 13 (a,b) are streak like artefacts and failure to recover the invisible boundary of the large blue disk highlighted in magenta inset. Our proposed reconstruction method using ResCorNet in Figure 13 (c) provides a notable improvement in the definition of the invisible boundary as well as the reduction in streak like background artefacts, which is consistent with its lowest MSE, highest PSRN and SSIM in Table 4. However, even in (c) parts of the invisible boundary of the faint large blue disk are missing (both left and right sides). We believe these artefacts could be due to the training set containing images of many overlapping ellipses, which means that examples of boundaries against the background are rare, only present for exterior ellipses. Furthermore, we note that the recovered shape has some resemblance with an ellipse. Both observations testify to limits of generalisation. The remaining disks are almost perfectly reconstructed by all methods. Overall, our proposed method while not without limitations is clearly superior in this generalisation scenario both in eye ball metric and the quantitative analysis in Table 4.

### 7. Realistic Data.

In this section we evaluate performance of our method on an *in-vivo* vessel data set. Our data set of vessel images is generated by randomly cropping images from the DRIVE data set for retinal vessel segmentation\(^\text{(10)}\). The re-sampled to $192 \times 96$ and normalised to $[0,1]$ vessel images constitute the top half of the test image, with bottom half all 0, resulting in test images of size $192 \times 192$, see Figure 14. We assume homogeneous speed of

ON LEARNING THE INVISIBLE IN LIMITED ANGLE PAT

Figure 13: 4-disk Generalisation - Visualisation of generalisation performance of correcting the visible and learning the invisible from ellipse data to 4-disk phantom ($\theta_{\text{max}} = \pi/4$): (a-c) different learned reconstructions.

(a) $\mathcal{N}\mathcal{N}_{\text{ResU-Net}}(p^\text{vis}_0)$
(b) $\mathcal{N}\mathcal{N}_{\text{ResU-Net}}(\tilde{Q}^\text{vis}_j)$
(c) $\mathcal{N}\mathcal{N}_{\text{ResCor}}(Q^\text{vis}_j)$

sound $c = 1500\text{m/s}$. The pressure time series is recorded every $h_t = 66.67\text{ns}$ by a line sensor, placed on top of the domain, with image matching resolution, i.e. $h_x = 10\mu\text{m}$ resulting in a $272 \times 192$ PAT data volume. The sensitivity angle $\theta_{\text{max}} = 2\pi/9$ is slightly smaller (and so is the visibility cone) than in the previous examples. 2000 images are used for training, 200 images for validation and 200 for testing.

We perform the visible reconstruction (VR) in fully wedge restricted Curvelet frame with 3 scales and 12 angles (at the 2nd coarse scale) with regularisation parameter $\tau = 1 \cdot 10^{-4}$ and 50 iterations. As we are in the imperfect learning scenario, we train a matching ResCorNet with loss (IPL) and weights $\alpha_F = 2$, $\alpha_{\text{SF}} = 2$ and $\alpha_C = 1$ in the same regime as outlined in section 6.

The Coronae coefficient based learning $\mathcal{N}\mathcal{N}_{\text{ResU-Net}}(\tilde{Q}^\text{vis}_j)$ and $\mathcal{N}\mathcal{N}_{\text{ResCor}}(Q^\text{vis}_j)$ outperforms image based learning $\mathcal{N}\mathcal{N}_{\text{ResU-Net}}(p^\text{vis}_0)$ as clearly visible in reconstructions in Figure 14. $\mathcal{N}\mathcal{N}_{\text{ResU-Net}}(p^\text{vis}_0)$ suffers from strong limited-view artefacts while $p^\text{vis}_{\text{TV}+}$ fails to recover the invisible vessel edges completely. Zooming in Figure 14 (red and green insets) corroborates that ResCorNet produces smooth background, sharp and detailed vessel edges and well matched contrasts. Some of these are also present in the other reconstructions but ResCorNet is unique in achieving all these goals simultaneously. This is reminiscent of ResCorNet performance for the ellipse data set (see subsection 6.3).

The quantitative analysis is summarised in Table 5. Most notably, we observe a large performance leap across all the measures between the methods learning Coronae coefficients and those learning images which reaffirms the benefits of Coronae representation in this context.

8. Conclusion. The paper rigorously builds a framework where images are nearly optimally represented in a fully wedge restricted Curvelet frame allowing splitting into visible/invisible components, which are optimally matched with the range/null space of the forward operator. All computations can be performed efficiently in Fourier domain. The network architecture is carefully designed to match both the visible/invisible split and the multiscale decomposition induced by the frame working with Coronae coefficients of the visible and invisible image components. Even sole learning of Coronae coefficients results in a substantial improvement on an image based learned post-processing using standard U-Net. The resulting

Figure 14: Vessels - Visualisation of the results for correcting the visible and learning the invisible on one test image (\( \theta_{\text{max}} = 2\pi/9 \)): (a) the initial pressure \( p_0 \) (ground truth), (b) the imperfect visible component reconstruction via (VR), (c) total variation regularised solution with non-negativity constraint, (d-f) different learned reconstructions.

We believe that our framework for this particular class of limited-view problems in photoacoustic tomography will further interest in applying similar ideas to other inverse problems, in particular application to limited-angle parallel CT is immediate. As with all learned methods, performance of our methods strongly depends on appropriateness and quality of the training scheme implementing the reconstructing the visible and learning the invisible strategy decouples the forward model from the training process at no detriment to reconstruction accuracy, which results in a stark performance benefit and a better interpretability compared to model based learning which is considered the gold standard (at least in terms of image quality) among learned reconstructions.

This manuscript is for review purposes only.
data. Finally, we note that extension of our method to 3D is conceptually straightforward and, as no expensive forward/adjoint operators are evaluated in training, it is computationally feasible.

Appendix A. Adjoint PAT Fourier Operator. By definition, the adjoint PAT Fourier operator ($\hat{A}^*$) satisfies the equality

\[ \langle \hat{g}, \hat{A} \hat{p}_0 \rangle = \langle \hat{A}^* \hat{g}, \hat{p}_0 \rangle \]  

for any real and even w.r.t. first variable functions $\hat{g}(\omega/c, k_S), \hat{p}(\omega/c, k_S), (\omega/c, k_S) \in \mathbb{R}_A \subset \mathbb{R}^d$ and $\hat{p}_0(k_\perp, k_S), (k_\perp, k_S) \in \mathbb{R}^d$ with sufficient regularity and decay (essentially in Schwarz space over $\mathbb{R}^d$) so that all the operations are well defined and $\langle \cdot, \cdot \rangle$ is the standard $L_2$ scalar product which we restrict to $\mathbb{R}_A$ for functions over $(\omega/c, k_S) \in \mathbb{R}^A$.

Substituting the action of the forward operator $\hat{A}$ on $\hat{p}_0, \hat{p}(\omega/c, k_S) = \hat{A}\hat{p}_0(k_\perp, k_S)$, on the left hand side of (A.1), we obtain

\[ \langle \hat{g}, \hat{A} \hat{p}_0 \rangle = \langle \hat{g}(\omega/c, k_S), \hat{p}(\omega/c, k_S) \rangle = 2 \int_{\mathbb{R}_0} \int_{\mathbb{R}^{d-1}} \hat{g}(\omega/c, k_S) \frac{\omega/c}{\sqrt{(\omega/c)^2 - |k_S|^2}} \hat{p}_0 \left( \sqrt{(\omega/c)^2 - |k_S|^2}, k_S \right) d(\omega/c) d k_S \]

where we used the even symmetry in the first variable of $\hat{g}(\omega/c, k_S), \hat{p}(\omega/c, k_S)$, which in turn implies even symmetry of $\hat{p}_0(k_\perp, k_S)$ (used later), to restrict the the first integral to non-negative real axis $\mathbb{R}_0$.

In the next step we make use of change of variables induced by the dispersion relation in the wave equation (3.3), $(k_\perp, k_S) \leftarrow \left( \sqrt{(\omega/c)^2 - |k_S|^2}, k_S \right), k_\perp \geq 0$, assumed continued with even symmetry for $k_\perp < 0$. The Jacobian of the change of coordinates yields

\[ dk_\perp = \frac{\omega/c}{\sqrt{(\omega/c)^2 - |k_S|^2}} d(\omega/c). \]

Executing the change of coordinates in the last line of (A.2), the factor gets absorbed into the volume element and we are left with

\[ \langle \hat{g}, \hat{A} \hat{p}_0 \rangle = \int_{\mathbb{R}^d} \hat{g}(|k|, k_S) \hat{p}_0(k_\perp, k_S) dk_\perp dk_S \]

= $\langle \hat{g}(|k|, k_S), \hat{p}_0(k_\perp, k_S) \rangle,$

where the factor 2 is accounted for by extension of the integration of the product of even functions from $\mathbb{R}_0$ back to $\mathbb{R}$. Comparing the above equation to the right hand side of defining equality (A.1), we immediately read out the action of the adjoint operator on $\hat{g}(\omega/c, k_S)$ as

\[ \hat{A}^* \hat{g}(\omega/c, k_S) = \hat{g}(|k|, k_S). \]
