Abstract

Missing data often results in undesirable bias and loss of efficiency. These results become substantial problems when the response mechanism is nonignorable, such that the response model depends on the unobserved variable. It is often necessary to estimate the joint distribution of the unobserved variables and response indicators to further manage nonignorable nonresponse. However, model misspecification and identification issues prevent robust estimates, despite carefully estimating the target joint distribution. In this study we model the distribution of the observed parts and derived sufficient conditions for model identifiability, assuming a logistic distribution of the response mechanism and a generalized linear model as the main outcome model of interest. More importantly, the derived sufficient conditions are testable with the observed data and do not require any instrumental variables, which have often been assumed to guarantee model identifiability but cannot be practically determined beforehand. To analyse missing data, we propose a new fractional imputation method which incorporates verifiable identifiability using only the observed data. Furthermore, we present the performance of the proposed estimators in numerical studies and apply the proposed method to two sets of real data, namely, Opinion Poll for the 2022 South Korean Presidential Election, and public data collected from the US National Supported Work Evaluation Study.

Keywords: counterfactual, exponential family, fractional imputation; generalized linear model; missing not at random.

1 Introduction

Handling missing data is an important issue in many research areas, including social science and biomedical studies, as an inappropriate analysis of missing data may yield erroneous results. This substantial issue could become more problematic when the response mechanism is nonignorable or missing not at random (MNAR), in which missingness is caused by the value that would have been observed (Ibrahim et al., 2005; Kim and Yu, 2011; Wang et al., 2014; Little and Rubin, 2019). Nonignorable nonresponse is extremely challenging to analyse because it often requires modelling the response model, as well as the distribution of the sampled data, to further construct the observed likelihood. Moreover, model identifiability may be violated even in a simple model. Therefore, model specification and identifiability are crucial for analysing nonignorable missing data.

To guarantee identifiability, several studies often assume the existence of a covariate, referred to as a non-response instrumental variable or shadow variable (Wang et al., 2014; Zhao and Shao, 2015; Miao and Tchetgen Tchetgen, 2016; Zhao and Ma, 2018; Li et al., 2021; Shetty et al., 2021). Although
the instrumental variable is beneficial in several cases, the determination of its existence is not straightforward, and even in this case, its detection from the observed data is an elusive task. In contrast, Miao et al. (2016) and Cui et al. (2017) derived certain conditions to identify models without using an instrumental variable. These studies assume the distribution of the outcome variable for the complete data and derive sufficient conditions for model identifiability. However, the assumptions are subjective. Moreover, we cannot check their validity because they are distributed for complete data.

Instead of modelling the complete data, numerous recently developed methods have modelled the distribution of the observed data, referred to as the respondents’ outcome model (Kim and Yu, 2011; Riddles et al., 2016; Morikawa and Kim, 2021; Li et al., 2021; Shetty et al., 2021). This modelling is advantageous because the observed data are available, and consequently, we can select a better model for the candidates using information criteria based on the observed data, such as the Akaike information criterion (AIC) and the Bayesian information criterion (BIC), or other variable selection methods such as the adaptive lasso (Zou, 2006). Moreover, we can explicitly identify the nonrespondents’ model when the respondents’ model can be fitted to a normal distribution, and the response model can be assumed as a logistic model (Im and Kim, 2017). This property is remarkable because the same technique used in Im and Kim (2017) can be applied to specify the nonrespondents’ outcome model.

This study derives the nonrespondents’ outcome model in an exponential family without any instrumental or shadow variables when the distribution of the observed data belongs to an exponential family, and the response mechanism follows a logistic distribution. For the estimation of model parameters, we employ fractional imputation (FI), which is among the most beneficial tools in missing data analysis for solving estimation equations (Kim, 2011; Im et al., 2018; Uehara et al., 2020; Sang et al., 2020). Detailed FI estimation procedures are introduced with variance estimation by applying the results of Riddles et al. (2016).

This paper proceeds as follows. Section 2 introduces the notation and defines model identifiability. In Section 3, we derive sufficient conditions to identify single-outcome models and subsequently extend it to mixture models. The estimation procedure using FI is presented in Section 4, and a numerical study using FI methods is explained in Section 5. Moreover, two real data examples are presented in Section 6. In conclusion, Section 7 summarizes the concluding remarks of this research. All technical proofs are relegated to the Appendix.

2 Basic Setup

Let \((x_i, y_i, \delta_i) (i = 1, \ldots, n)\) be \(n\) independently realised values of random variables \((x, y, \delta)\), where \(y\) denotes a response variable subject to missingness, \(\delta\) denotes a response indicator of \(y\) that equals 1(0) if \(y\) is observed (missing), and \(x\) represents a vector of completely observed covariates. Additionally, we assume that the response mechanism follows a logistic model:

\[
\text{logit} \{P(\delta = 1 | x, y; \alpha, \beta)\} = h(x; \alpha) + \beta y,
\]  

where \(\text{logit}(z) := \log \{z/(1 - z)\}\) for all \(0 < z < 1\) and \(h(x; \alpha)\) is injective with respect to \(\alpha\) and is known up to a finite-dimensional parameter \(\alpha\). This logistic model has been used in many previous studies, for example, Kim and Yu (2011); Shao and Wang (2016) and Wang et al. (2021).
Suppose that the outcome distribution of the respondent given the co-
variates \([y_i \mid x_i, \delta_i = 1]\) belongs to the exponential family in the form
\[
f(y_i \mid x_i, \delta_i = 1; \gamma) = \exp \left\{ \frac{y_i \theta_i - b(\theta_i)}{a(\gamma)} + c(y_i; \gamma) \right\}.
\] (2)
where \(\theta_i = \theta(y_i)\), \(\eta_i = \sum_{l=1}^{L} y_i_{l}(x_i)\alpha_l\), \(\alpha(\tau) = \tau^{-1}w^{-1}\), \(\kappa = (\kappa_1, \ldots, \kappa_L)^\top\)
and \(\gamma = (\tau, \kappa')^\top\). For ease of exposition, we assume that \(w_1 = 1\) throughout
this study. This class includes several distributions, such as binomial,
normal, gamma, and Poisson distributions. The function \(\theta\) is defined according
to the purpose of the statistical analysis.

Referring to Riddles et al. (2016), we can express the non-respondents’
outcome model, \([y \mid x, \delta = 0]\), as the product of the respondents’ outcome
model and the odds of nonresponse probability such that
\[
f(y \mid x, \delta = 0) = f(y \mid x, \delta = 1) \frac{O(x, y)}{E\{O(x, y) \mid x, \delta = 1\}},
\] (3)
where \(O(x, y) = P(\delta = 0 \mid x, y)/P(\delta = 1, x, y)\). When the study variable
of the respondents’ outcome model is a member of the exponential family
(2) and the response mechanism follows the logistic model (1), the outcome
model of the non-respondents in (3) can be also expressed as the same
exponential family as the respondents’ outcome model, but with a different
parameterization:
\[
f(y \mid x, \delta = 0) = f(y \mid x, \delta = 1) \frac{\exp \{-h(x; \alpha) - \beta y\}}{\exp \{-h(x; \alpha) - \beta y\} f(y \mid x, \delta = 1)dy} \propto \exp \left\{ \tau \left\{ y (\theta - \beta \tau^{-1}) - b (\theta - \beta \tau^{-1}) \right\} + c(y; \tau) \right\}.
\] (4)

Im and Kim (2017) proposed the same idea for a specific case in which
\([y \mid x, \delta = 1]\) is a normal distribution and \([\delta = 1 \mid y, x]\) is a logistic model.
Parameters \((\alpha^\top, \beta, \gamma^\top)^\top\) are estimated by solving the mean score equation
\(S(\alpha, \beta) = 0\), where
\[
\hat{S}(\alpha, \beta) = \sum_{i=1}^{n} \delta_i S_i(\alpha, \beta; x_i, y_i) + (1 - \delta_i) E \{S_i(\alpha, \beta; x_i, y_i) \mid x_i, \delta_i = 0\} ,
\]
\(S_i(\alpha, \beta; x, y) = \frac{\delta - P(\delta = 1 \mid x, y)}{P(\delta = 1 \mid x, y) (1 - P(\delta = 1 \mid x, y))} \frac{\partial P(\delta = 1 \mid x, y; \alpha, \beta)}{\partial (\alpha^\top, \beta^\top)},\)
\(\gamma = \arg \max_{\gamma} \sum_{i=1}^{n} \delta_i \log f(y_i \mid x_i, \delta_i = 1; \gamma)\). We assume that the model
can be identified if
\[
P(\delta = 1 \mid x, y; \alpha, \beta)f(y \mid x; \alpha, \beta, \gamma) = P(\delta = 1 \mid x, y; \alpha', \beta', \gamma')f(y \mid x; \alpha', \beta', \gamma') \text{ with probability 1}
\]
implies that \((\alpha^\top, \beta, \gamma^\top)^\top = (\alpha'^\top, \beta', \gamma'^\top)^\top\). Note that simple parametric
models of \(P(\delta = 1 \mid y, x)\) and \(f(y \mid x)\) may not be identified, for instance,
Example 1 in Wang et al. (2014).

3 Identification condition

In this section, we derive the sufficient conditions representing model identifi-
ability, while considering the outcome models that belong to the exponential
family (2), and further extend the result to the mixture models.
3.1 Single Outcome Model

The following theorem is a general result of the model identifiability for the outcome model (2).

**THEOREM 1.** Suppose that the response mechanism is (1) and the distribution of \([y \mid x, \delta = 1]\) is identifiable with a density that belongs to the exponential family (2). Then, this model is identifiable if the following condition holds for all \(\alpha, \alpha', \beta, \beta', \gamma\).

\[
\varphi(\alpha, \beta, \gamma) = \varphi(\alpha', \beta', \gamma) \Rightarrow \beta = \beta',
\]

where

\[
\varphi(\alpha, \beta, \gamma) = h(x; \alpha) - \tau b \left\{ \theta \left( \sum_{l=1}^{L} \eta_l(x) \kappa_l \right) - \frac{\beta}{\tau} \right\}.
\]

A vital implication of Theorem 1 is that the identifiability of the model is equivalent to that of \(\varphi(\alpha, \beta, \gamma)\). Furthermore, the model identification of \(\varphi\) can be verified with respect to only \(\beta\). Based on Theorem 1, we can conveniently check the identification condition for almost all distributions that belong to the exponential family, even if the covariates \(x\) contain both discrete and continuous variables. If the covariates \(x\) contain only discrete variables, we can ascertain whether the number of unknown variables \((\alpha', \beta')^\top\) is less than or equal to the number of values obtained by the covariates \(x\). Additionally, we provide Corollary 1, which specifically assumes that the outcome model follows a normal distribution because it requires careful attention, as detailed further in Example 1.

**COROLLARY 1.** Suppose that the response mechanism is (1), \(h(x; \alpha)\) is a polynomial, and the outcome model of the respondents is \(N(\mu(x; \gamma), \sigma^2)\), where the link function represents the identity \(\theta(\eta) = \eta\) such that \(\mu(x; \gamma) = \sum_{l=1}^{L} \eta_l(x) \kappa_l\). Then, condition (5) holds if an index \(l = 1, \ldots, L\) exists, such that \(\eta_l(x)\) is continuous and is not represented by \(h(x; \alpha)\) for all \(\alpha\).

We introduce certain examples that are commonly used in the generalized linear model (GLM) to formulate Theorem 1 and Corollary 1.

**EXAMPLE 1.** Considering the same setting as in Corollary 1, the function \(\varphi\) in Theorem 1 can be expressed as

\[
\varphi(\alpha, \beta, \gamma) = h(x; \alpha) + \beta \sum_{l=1}^{L} \eta_l(x) \kappa_l - \frac{\sigma^2 \beta^2}{2}.
\]

 Particularly, condition (5) holds if \(\sum_{l=1}^{L} \eta_l(x) \kappa_l\) contains a term that is not included in \(h(x; \alpha)\). For instance, \(\sum_{l=1}^{L} \eta_l(x) \kappa_l = \kappa_0 + \kappa_1 x + \kappa_2 x^2 (\kappa_2 \neq 0)\) and \(h(x; \alpha) = \alpha_0 + \alpha_1 x\) satisfy this condition if the covariate \(x\) is continuous. If covariate \(x\) is binary, the identification condition does not hold owing to the three unknown variables, \((\alpha_0, \alpha_1, \beta)\). Additionally, the model is not identifiable for \(\kappa_2 = 0\) even if covariate \(x\) is continuous. This is identical to the example discussed by Morikawa and Kim (2021).

**EXAMPLE 2.** Suppose that \([y \mid x, \delta = 1] \sim B(1, p(x))\), which belongs to the exponential family, with \(\tau = 1\), \(\theta = \log p/(1 - p)\), \(b(\theta) = \log \{1 + \exp(\theta)\}\), \(c(y; \gamma) = 0\), \(\theta(\eta) = \eta\). Accordingly, we check the identifiability of this model; the function \(\varphi\) in Theorem 1 can be expressed as:

\[
\varphi(\alpha, \beta, \gamma) = h(x; \alpha) - \log \left\{ 1 + \exp \left( -\beta + \sum_{l=1}^{L} \eta_l(x) \kappa_l \right) \right\}.
\]

For instance, condition (5) holds if polynomials \(h(x; \alpha)\) and \(\eta_l(x)\) contain continuous variables.
For non-ordered categorical variables, such as sex and area, the outcome models for each categorical variable should be assumed, as discussed in Section 5. For instance, if \( z \) denotes sex and \( x \) represents another continuous covariate, we can model various mean structures \( \kappa_0 + \kappa_1x \) for men and \( \kappa_0 + \kappa_1x + \kappa_2z \) for women rather than \( \kappa_0 + \kappa_1x + \kappa_2z \). In such cases, we provide sufficient conditions for model identifiability.

**EXAMPLE 3.** Suppose that non-ordered categorical variables occur in \( D \) cases with \( z = 1, 2, \ldots, D \), indicating one of the \( D \) cases. Then, the response mechanism is (1) and \( h(x; \alpha) = \sum_{d=1}^{D} \eta_d(x; \alpha_d) \), and the outcome density of the respondents can be expressed as

\[
\prod_{d=1}^{D} \left[ \frac{1}{\sqrt{2\pi\sigma_d^2}} \exp \left\{ -\frac{(y - \mu_d(x; \kappa_d))^2}{2\sigma_d^2} \right\} \right]^{I(z=d)},
\]

where \( \kappa_d \) and \( \sigma_d^2 \) represent the mean function and variance parameter, respectively, and \( I(\cdot) \) denotes the indicator function. As is a normal distribution with mean \( \sum_{d=1}^{D} I(z = d)\mu_d(x; \kappa_d) \) and variance \( \sum_{d=1}^{D} I(z = d)\sigma_d^2 \).

Consequently, the function \( \varphi \) in Theorem 1 can be expressed as

\[
\varphi(\alpha, \beta, \gamma) = h(x; \alpha) + \beta \sum_{d=1}^{D} I(z = d)\mu_d(x; \kappa_d) - \frac{\beta^2}{2} \sum_{d=1}^{D} I(z = d)\sigma_d^2.
\]

Similar to Corollary 1, this model is identifiable if an index \( l = 1, \ldots, D \) exists, such that \( \mu_l(x; \kappa_l) \) is continuous and not represented by \( h_l(x; \alpha_l) \) for all \( \alpha_l \).

**EXAMPLE 4.** Suppose that non-ordered categorical variables occur in \( D \) cases with \( z = 1, 2, \ldots, D \), which indicates one of the \( D \) cases. The response mechanism is (1) and \( h(x; \alpha) = \sum_{d=1}^{D} \eta_d(x; \alpha_d) \), and \( [y | x, \delta = 1] \sim B(1, p(x)) \), where \( \logit\{p(x)\} = \sum_{d=1}^{D} I(z = d)\sum_{l=1}^{K_d} \eta_d(x)\kappa_{ld} \). The function \( \varphi \) in Theorem 1 can be expressed as

\[
\varphi(\alpha, \beta, \gamma) = \sum_{d=1}^{D} h_d(x; \alpha_d) - \log \left\{ 1 + \exp \left( -\beta + \sum_{d=1}^{D} I(z = d)\sum_{l=1}^{L_d} \eta_{ld}(x)\kappa_{ld} \right) \right\}.
\]

Similar to Example 3, the model can be more easily identified than in the case with no categorical measurement variables.

### 3.2 Mixture outcome models

In this subsection, we derive sufficient conditions for model identifiability when the response mechanism is (1) and the outcome model of the respondents \( [y | x, \delta = 1; \gamma] \) is a mixture distribution of the exponential family (2)

\[
\sum_{k=1}^{K} \pi_k \exp \{\tau_k \{y\theta_k - b(\theta_k)\} + c(y; \tau_k)\},
\]

where \( \pi = (\pi_1, \ldots, \pi_K)^T \) is the mixing proportion of the mixing distributions, \( \tau = (\tau_1, \ldots, \tau_K)^T \) denot the model parameters, and \( \eta_k = \sum_{d=0}^{m(k)-1} \eta_{d}\kappa_{d}. \kappa_{k} = \left( \kappa_{0k}, \kappa_{1k}, \ldots, \kappa_{m(k)-1 k} \right)^T \) are link functions and its parameters, \( \gamma = (\kappa^T, \tau^T, \pi^T, K)^T \) is a vector of all the parameters, and \( m(k) \) indicates a dimension of the vector \( \kappa_k \). The following theorem is the most general result representing the identifiability of the mixture model; its results are consistent with those of Theorem 1 for \( K = 1 \).
THEOREM 2. Suppose that the response mechanism is (1) and the distribution of \( y \mid x, \delta = 1 \) is (6) and identifiable. Then, this model is identifiable if the following condition holds for all \( \alpha, \alpha', \beta, \beta', \gamma \):

\[
g(\alpha, \beta, \gamma) = g(\alpha', \beta', \gamma) \Rightarrow \beta = \beta',
\]

where

\[
g(\alpha, \beta, \gamma) = h(x; \alpha) - \log \left[ \sum_{k=1}^{K} \pi_k \exp \left\{ -\tau_k b(\theta_k) + \tau_k b \left( \theta_k - \frac{\beta}{\tau_k} \right) \right\} \right].
\]

Because the most popular and commonly used mixture model is a normal mixture, we discuss more details of the identification conditions in the case where \( y \mid x, \delta = 1; \gamma \) is a normal mixture distribution

\[
[y \mid x, \delta = 1; \gamma] \sim \sum_{k=1}^{K} \pi_i N(\mu_k(x; \kappa_k), \sigma_k^2),
\]

where \( \mu_k(x; \kappa_k) \) denotes a polynomial \( \sum_{i=0}^{m(k)-1} \eta_{lk}(x)\kappa_{lk}, \sigma^2 = (\sigma_1^2, \ldots, \sigma_K^2)^\top \) represents a vector of variance, and \( \gamma = (\kappa^\top, \sigma^\top, \tau^\top, K) \) denotes the vector of all parameters. In this case, we obtain the following result by applying Theorem 2.

COROLLARY 2. Suppose that the response mechanism is (1) and the distribution of \( y \mid x, \delta = 1 \) is (7) and identifiable. Then, this model is identifiable if the following condition holds for all \( \alpha, \alpha', \beta, \beta', \gamma \):

\[
g(\alpha, \beta, \gamma) = g(\alpha', \beta', \gamma) \Rightarrow \beta = \beta',
\]

where

\[
g(\alpha, \beta, \gamma) = h(x; \alpha) - \log \left\{ \sum_{k=1}^{K} \pi_l \exp \left\{ -\sum_{i=0}^{m(k)-1} \eta_{lk}(x)\kappa_{lk} + \frac{\beta^2\sigma_k^2}{2} \right\} \right\}.
\]

Hereafter, we consider a practically useful setup, where the basis functions of \( h(x; \alpha) \) and \( \eta_{lk}(x; \kappa_k) \) have the form of \( \prod_{s \in x} x_{s}^{s} \) and \( s_i \) represents a nonnegative integer. For ease of exposition, let \( h(x; \alpha) \) and \( \mu_i(x; \kappa_i) \) be polynomial functions. We define two classes of basis functions:

\[
\mathcal{H} := \{ h_{l'}(x) \in \mathcal{X}; l' = 1, \ldots, L' \} \cup \{1\},
\]

and

\[
\mathcal{M} := \{ \eta_{lk}(x) \in \mathcal{X}; l = 0, 1, \ldots, m(k) - 1, k = 1, \ldots, K \} \setminus \mathcal{H}.
\]

Moreover, \( \mu_i(x; \kappa_i) \) is substituted into \( \mu_i(x; \kappa_i) = \mu_l^\mathcal{H}(x; \kappa_i) + \mu_l^\mathcal{M}(x; \kappa_i) \), where each \( \mu_l^\mathcal{H} \) and \( \mu_l^\mathcal{M} \) belong to \( \mathcal{H} \) and \( \mathcal{M} \), respectively. When the distribution of \( x \) is discrete, comparing the number of variables and the values of \( x \) is sufficient; therefore, we only consider the following case:

(C1) The distribution of \( x \) is continuous.

The next theorem is a more specific consideration of Corollary 2.

THEOREM 3. Suppose that the response mechanism is (1) and the distribution of \( y \mid x, \delta = 1 \) is identifiable and has a normal mixture density in (7). Then, this model is identifiable if (C1)–(C2) and one of (C3)–(C4) holds:
(C2) \( \mathcal{M} \neq \emptyset \);
(C3) The sign of \( \beta \) is known;
(C4) \( \{\mu_i^M(x; \kappa_1); \ i = 1, \ldots, K\} \neq \{-\mu_i^M(x; \kappa_1); \ i = 1, \ldots, K\} \).

Confirming only (C2) may be sufficient because not satisfying (C4) may be rare in practical applications. The following example shows an unidentifiable model that satisfies condition (C2) but does not satisfy (C3)–(C4).

**EXAMPLE 5.** Suppose that the outcome model of the respondents is
\[
\pi_1 \mathcal{N}(x^2, \sigma_1^2) + \pi_2 \mathcal{N}(-x^2, \sigma_2^2).
\]
Consider the following two response models.

Model 1 : \( \text{logit} \{P(\delta = 1 | x, y)\} = x + y \);
Model 2 : \( \text{logit} \{P(\delta = 1 | x, y)\} = x - y \).

This model satisfies condition (C2) because \( \mathcal{M} = \{x^2\} \) and \( \mathcal{H} = \{1, x\} \) but does not satisfy (C3)-(C4) because we do not know the signs of \( \beta \) and \( \{\mu_i^M(x; \kappa_1); \ i = 1, \ldots, K\} = \{x^2, -x^2\} \). The sufficient condition in Corollary 2 is not satisfied if
\[
\frac{1}{2} \sigma_1^2 + \log \pi_1 = \frac{1}{2} \sigma_2^2 + \log \pi_2
\]
holds; therefore, the model is unidentifiable.

The following example shows an unidentifiable model that does not satisfy (C2):

**EXAMPLE 6.** Suppose that the outcome model of the respondents is \( \pi_1 \mathcal{N}(x, \sigma_1^2) + \pi_2 \mathcal{N}(2x, \sigma_2^2) \), considering two response models.

Model 1 : \( \text{logit} \{P(\delta = 1 | x, y)\} = x + y \);
Model 2 : \( \text{logit} \{P(\delta = 1 | x, y)\} = 4x - y \).

This model does not satisfy the condition (C2) because \( \mathcal{M} = \emptyset \) and \( \mathcal{H} = \{1, x\} \). The sufficient condition in Corollary 2 is not satisfied if
\[
\frac{1}{2} \sigma_1^2 + \log \pi_1 = \frac{1}{2} \sigma_2^2 + \log \pi_2
\]
holds; therefore, the model is unidentifiable.

Although Example 6 and Theorem 3 indicate the importance of condition (C2), eliminating this condition enables more flexible modelling. Therefore, we derive sufficient conditions for the identifiability of a model that is an integration of simple linear regression models.

\[
[y | x, \delta = 1; \gamma] \sim \sum_{k=1}^{K} \pi_k \mathcal{N}(\kappa_{0k} + \kappa_{1k}x, \sigma_k^2), \quad (8)
\]
and \( \mathcal{H} = \{1, x\} \), which do not satisfy (C2). We derive the conditions separately, as the sufficient conditions for model identifiability differ for \( K \geq 3 \) and \( K = 2 \).

**THEOREM 4.** Suppose that the response mechanism is (1) and the distribution of \( [y | x, \delta = 1] \) is identifiable and has a normal mixture density in (8) with the number of mixture components \( K \geq 3 \). We further assume that \( \mathcal{H} = \{1, x\} \), \( \kappa = (\kappa_{11}, \kappa_{12}, \ldots, \kappa_{1K})^\top \) is a vector of first-order coefficients and \( \kappa_{1i} \neq \kappa_{1j} \) \( (i \neq j) \). Then, the model is identifiable if at least one of the following conditions is satisfied.
Sign of $\beta$ is known;

For all $K \times K$ permutation matrices $P$ and for all $r \in \mathbb{R}$,

$$(P + I) \tilde{\kappa} \neq r \mathbf{1}_K,$$

where $\mathbf{1}_n$ denotes the $n \times 1$ vector.

To clarify the second condition, we consider $K = 3$ and assume that $\kappa_{11} > \kappa_{12} > \kappa_{13}$, without loss of generality. If $P$ is defined as

$$P = \begin{pmatrix} 0 & 0 & 1 \\ 0 & 1 & 0 \\ 1 & 0 & 0 \end{pmatrix},$$

we obtain $(P + I) \tilde{\kappa} = (\kappa_{11} + \kappa_{13}, 2\kappa_{12}, \kappa_{11} + \kappa_{13})^T$. The second condition is satisfied, unless $r = \kappa_{11} + \kappa_{13}$ or $2\kappa_{12} = \kappa_{11} + \kappa_{13}$. More importantly, it does not generally hold and can be tested using the observed data.

However, for $K = 2$, the second condition in Theorem 4 does not hold for any model in $[y | x, \delta = 1]$, which can be shown by assuming that $\kappa_{11} > \kappa_{12}$ without loss of generality. Based on a similar argument, we derive $(P + I) \tilde{\kappa} = (\kappa_{11} + \kappa_{12}, \kappa_{11} + \kappa_{12})^T = r \mathbf{1}_2$, where:

$$P = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \quad r = \kappa_{11} + \kappa_{12}.$$ 

Therefore, the second condition does not hold for any model $[y | x, \delta = 1]$. Therefore, there is a need for more careful investigation of $K = 2$.

THEOREM 5. Suppose that the response mechanism is (1) and the distribution of $[y | x, \delta = 1]$ is identifiable and has a normal mixture density in (8) with the number of mixture components $K = 2$. We further assume that $H = \{1, x\}$, $\mu_1(x, \kappa_1) = \kappa_0 + \kappa_{11}x$ ($\kappa_{11} \neq 0$), $\mu_2(x, \kappa_2) = \kappa_0 + \kappa_{12}x$ ($\kappa_{12} \neq 0$), and $h(x; \alpha) = \alpha_0 + \alpha_1x$ ($\alpha_1 \neq 0$). Then, the model is identifiable if the following conditions hold.

1 $\kappa_{11} \neq \kappa_{12}$;
2 $\sigma_1 = \sigma_2 \Rightarrow \pi_1 \neq \pi_2$;
3 $\sigma_1 \neq \sigma_2 \Rightarrow (\log \pi_2 - \log \pi_1) (\sigma_1^2 - \sigma_2^2)^{-1} \leq 0$.

Overall, the conditions required in Theorems 5 are more difficult than those required in Theorems 4. Although these conditions can be verified using the observed data, they would be redundant.

4 Estimation

This section presents an estimation procedure that employs Kim (2011)’s fractional imputation approach. Parameter estimates can be obtained using the mean score function presented in Riddles et al. (2016). Instead of directly solving the mean score function with the observed data, we use an imputation-based EM method which uses both fractionally imputed and observed data. To explain the proposed method, we first define a mean score function with unknown parameters $(\alpha, \beta)$, such that

$$S_i(\phi) = S(\alpha, \beta; x_i, y_i, \delta_i).$$

$$= \frac{\partial}{\partial(\alpha, \beta)} \left\{ \delta_i \log \pi(x_i, y_i; \alpha, \beta) + (1 - \delta_i) \log (1 - \pi(x_i, y_i; \alpha, \beta)) \right\},$$

$$= \{ \delta_i - \pi(x_i, y_i; \alpha, \beta) \} z(x_i, y_i; \alpha, \beta),$$
where
\[
\pi(x_i, y_i; \alpha, \beta) := P(\delta_i = 1 \mid x_i, y_i; \alpha, \beta),
\]
\[
z(x_i, y_i; \alpha, \beta) := \frac{1}{\pi(x_i, y_i; \alpha, \beta) \{1 - \pi(x_i, y_i; \alpha, \beta)\}} \frac{\partial \pi(x_i, y_i; \alpha, \beta)}{\partial (\alpha^\top, \beta)}.
\]

The proposed EM algorithm can then be implemented in the following steps.

(Step 1) (E-step) Obtain the mean score function for the non-respondents’ outcome and the response models. The mean score function can be expressed as
\[
\overline{S}(\phi) = \sum_{i=1}^{n} \left[ \delta_i S_i(\phi) + (1 - \delta_i) E\{S_i(\phi) \mid x_i, \delta_i = 0\} \right],
\]
where
\[
E\{S_i(\phi) \mid x_i, \delta_i = 0\} = \frac{\int S_i(\phi) f(y \mid x_i, \delta_i = 1) O(x_i, y; \theta) dy}{\int f(y \mid x_i, \delta_i = 1) O(x_i, y; \theta) dy},
\]
where \(O(x, y; \phi) = 1/\pi(x, y; \phi) - 1\). Upon generating imputed values from \(f(y \mid x, \delta = 0)\), the mean score function can be computed as follows:
\[
\overline{S}(\phi) = \sum_{i=1}^{n} \left\{ \delta_i S_i(\phi, y_i; x_i) + (1 - \delta_i) \frac{1}{M} \sum_{j=1}^{M} S_i(\phi, y_i^{(j)}; x_i) \right\},
\]
where \(y_i^{(j)}\) is the \(j\)-th imputed value \((j = 1, \ldots, M)\) for unit \(i\).

(Step 2) (M-step) Update the estimates of the model parameters by solving the mean score functions.

(Step 3) Repeat (Step 1) and (Step 2) until they achieve a convergence criterion.

Under some regularity conditions, the estimator \(\hat{\phi}\) obtained by FI has asymptotic normality, as proven by Riddles et al. (2016):
\[
\sqrt{n}\left(\hat{\phi} - \phi_0\right) \rightarrow N(0, \Sigma_\phi),
\]
where the form of the asymptotic variance is detailed in Appendix 7.

5 Numerical Study

In this section, we conduct numerical studies to evaluate the performance of the proposed FI method. We assume that the response mechanism follows a logistic distribution.
\[
\text{logit}\{P(\delta = 1 \mid x, y; \alpha, \beta)\} = \alpha_0 + \alpha_1 x + \beta y,
\]
where \(x\) denotes a one-dimensional covariate. We conduct three scenarios, S1–S3 with varying outcome models, as follows:

S1: The distribution of \(y \mid x, \delta = 1\) is \(N(\kappa_0 + \kappa_1 x + \kappa_2 x^2, \sigma^2)\), where \(\{\kappa_0, \kappa_1, \sigma^2\}^\top = (0, 0.4, 1/\sqrt{2})^\top\) and \(\kappa_2\) (identifiability) are 0.1 (weak), 0.5 (moderate), and 1.0 (strong), the distribution of the covariate \(x\) is \(N(0, 1^2)\), and the true parameter of the response mechanism is \(\{\alpha_0, \alpha_1, \beta\}^\top = (0.68, 0.19, 0.24)^\top\).
S2: The distribution of \[ y \mid x, \delta = 1 \] follows a binomial distribution \( B(1,1/(1 + \exp(-\kappa_0 - \kappa_1 x))) \), where \( (\kappa_0, \kappa_1)^\top = (-0.21, 5.9)^\top \), the distribution of the covariate \( x \) is \( N(0, 1^2) \), and the true parameter of the response mechanism is \( (\alpha_0, \alpha_1, \beta)^\top = (0.7, 0.39, 0.39)^\top \).

S3: The distribution of \[ y \mid x, \delta = 1 \] follows a normal mixture distribution \( 0.35N(1 - 1.4x, 1/\sqrt{2}) + 0.65N(-1.5 - 0.5x + x^2, 1/\sqrt{2}) \), where the distribution of the covariate \( x \) is \( N(0, 1^2) \) and the true parameter of the response mechanism is \( (\alpha_0, \alpha_1, \beta)^\top = (0.9, -0.26, 0.2)^\top \).

We generate \( B = 1,000 \) independent Monte Carlo samples with a sample size of \( n = 500 \). The average response rate is approximately 0.7 for all scenarios. We compare our proposed FI estimators with complete case (CC) estimators, which use only complete cases. For comparison, we consider two parameters: the expectation of the missing variable \( y \), \( \mu_y \), and the response model coefficient \( \beta \) associated with the missing variable \( y \).

Table 1 reports the bias, root-mean-square error (RMSE), and coverage rates with a 95% confidence interval. Although the naive CC estimators have large biases in all scenarios, the proposed FI estimators yield asymptotically unbiased estimates, except for non-identifiable situations.

Based on the discussion in Example 1, we demonstrate that the model in S1 is unidentifiable for \( \kappa_2 = 0 \). Moreover, as \( \kappa_2 \) tends to 0, the identifiability becomes weaker, hence yielding inaccurate estimates. For the estimations of \( \mu_y \), the FI estimators performed adequately in all scenarios, and the results for the coverage rate were acceptable. Regarding the estimations of \( \beta \), the bias is still less in all scenarios. However, the RMSE in S2 takes large values owing to the lack of information on binary outcomes.

Table 1: Results of S1–S3: bias, root mean square error (RMSE), and coverage rate (CR,%) with 95% confidence interval are reported. CC, complete case; FI: fractional imputation.

6 Real Data Analysis

6.1 Election Poll Data

We apply the proposed method to opinion poll data collected to predict the 2022 South Korean presidential election. Specifically, data were obtained from a telephone survey with a response rate of 8.96% from 896 individuals among 10,000 potential voters. The dataset includes respondents’ voting intentions regarding electoral participation, voting preferences, and demographic information, such as sex, area, and age.

The respondents’ voting preferences, denoted by $y$, were categorised into binary responses: 1 for the candidate of the ruling party and 0 for other candidates. Additionally we redefine the intention of electoral participation, denoted by $\delta$, such that it equals 1 if a respondent is likely to participate in the election, and 0 otherwise. We assume that we do not observe $y$, whose voting intention, $\delta$, is 0. Among the 896 respondents, we observe $y$ for 841 (93.9%) respondents and do not observe $y$ for the remaining 55 (6.1%) respondents. Moreover, we implicitly assume a nonignorable missing mechanism, such that voting intention is closely related to the respondents’ voting preferences.

The covariate $age (\geq 19)$ is continuous, $sex$ is a binary non-ordered categorical variable which represents male status or not, and $area$ is another non-ordered categorical variable with three merged administrative districts in South Korea. The “true” averaged voting preference rate of $E(y)$ is $\hat{\theta}_n = 0.300 (= 269/896)$ calculated using the complete data, and the naive average voting rate is $\hat{\theta}_{naive} = 0.317 (= 267/841)$ calculated using the observed data with $\delta = 1$.

To apply our proposed method, we define a non-ordered categorical variable $z$ with six values that integrate the $sex$ and $area$ variables. Subsequently, we assume a binomial distribution $B(1, p_1(x, z))$ as the outcome model, where

$$\text{logit} \{ p_1(x, z) \} = \sum_{d=1}^{6} I(z = d) \sum_{l=0}^{4} \kappa_{ld} x^l,$$

and $\kappa_{ld}$ is the coefficient of the logistic regression for the $l$-th power of the covariate for $z = d$, and $x$ represents the standardisation of $age$. For each value of $z$, we select the most suitable logistic regression model by AIC in a stepwise algorithm among $2^5 - 1$ models. The resulting logistic regression functions vary for each categorical variable. For example, the most suitable model is $-0.12 - 1.09x - 0.69x^2 + 0.55x^3$ for $z = 1$, and $-0.68 - 0.85x - 0.66x^2$ for $z = 6$.

We assumed that the response model

$$\text{logit} \{ P(\delta = 1 \mid x, z, y; \alpha, \beta) \} = \sum_{d=1}^{6} I(z = d) (\alpha_0d + \alpha_1d x) + \beta y,$$

and further estimate $(\alpha^\top, \beta)^\top$ and the mean voting preference using the proposed FI method. As explained in Example 4, this model can be identified without using instrumental variables.

Table 2 presents the point estimates and 95% confidence intervals of the model parameters and $E[y]$. The 95% confidence intervals for $z = 5$ and $z = 6$ are wider than the others, owing to the smaller sample size. We can assert that the proposed FI method performs well because the confidence interval of $E[y]$ contains the “true” average voting rate $\hat{\theta}_n = 0.300$. Although the point estimator of $\beta$ significantly deviates from 0, we cannot determine whether it is MAR or NMAR because the 95% confidence interval contains 0 in this real data application.

6.2 National Supported Work Data

In the second application, we use publicly available data collected to evaluate the National supported work (NSW) demonstration project Lalonde (1986). The response indicator δ denotes a treatment indicator, and the covariates of the dataset are age, education, black, nodegree, where age and education are continuous, and black and nodegree are non-ordered categorical binary response variables that represent whether the race of a participant is black and they do not take degree or not, respectively. The integration of black and nodegree defines a new non-ordered categorical variable z with four values. The covariates x₁ and x₂ represent the standardisation of age and education, respectively. We also define the outcome value y by the logarithmic transformation of earnings in 1978 using any non-zero. The response rate was approximately 43.7% for the 526 experimental participants.

We selected the most suitable model using the AIC and confirmed the identifiability of the model. As explained in Theorem 3, the most suitable model must satisfy (C2) and (C4): Hence, we verify how far the most suitable model and the model that does not satisfy (C2) or (C4) are separated. The identifiability of the model. As explained in Theorem 3, the most suitable model using the AIC and confirmed the identifiability of the model. As explained in Theorem 3, this model is identifiable. For z = 1 and z = 3 is

\[
\begin{align*}
    \frac{z}{z} = 1 : 0.25N(7.13 - 0.68x₁ - 0.55x₂ + 0.06x₁^2, 0.90^2) \\
    + 0.3N(9.21 - 0.02x₁^2, 0.20^2) + 0.42N(8.86 + 0.44x₂ + 0.16x₁x₂, 0.68^2); \\
    \frac{z}{z} = 3 : 0.54N(0.62 + 0.07x₁^2 - 0.27x₅^2 + 0.88x₁^3 + 0.44x₁x₂, 0.21^2) \\
    + 0.45N(8.03 - 0.54x₂ + 0.08x₁^2 - 0.20x₅^2, 0.48^2).
\end{align*}
\]

As explained in Theorem 3, this model is identifiable. For z = 2 and z = 3, the largest AIC models in unidentifiable models that do not satisfy (C2) or (C4) of Theorem3 are 131.58 and 90.23. However, the most suitable models are 119.76 and 79.48, respectively. The naive average of the outcome is \( \bar{\mu}_{naive} = 8.52 \), calculated using only the respondents’ data. Figure 1 reports the residual plots for each categorical variable, which show the goodness of fit of the normal mixture. We assume that the response model

\[
\text{logit } \{P(\delta = 1 \mid x₁, x₂, z, y, \alpha, \beta)\} = \sum_{d=1}^{4} l(z = d) (\alpha_{0d} + \alpha_{1d}x₁ + \alpha_{2d}x₂ + \beta y,
\]

12
and further estimate \((\alpha^\top, \beta)^\top\) and the mean of \(y\) using the proposed FI method.

Table 3 reports the point estimate and 95% confidence intervals for each target parameter. A smaller sample size of \(z = 4\) widens the 95% confidence intervals of \(\alpha_{24}\). Although the point estimate of \(\beta\) significantly deviates from 0, we cannot determine whether it is MAR or NMAR because the 95% confidence interval contains 0.

7 Discussion

The analysis of nonignorable missing data requires strong assumptions on both the response mechanism and the distribution of the samples. In this paper, we derived the sufficient conditions for model identifiability with the generalized linear model and the logistic response mechanism. Subsequently, we extended the outcome model to allow for mixture of the distributions that belong to an exponential family and discussed the model identifiability of the normal mixture models. The main advantage of this proposed method is that we do not need to find the instrumental variable and can check validity of the model by using observed data. Additionally, we applied the proposed method on two real datasets to validate its effectiveness.

Although we confined the response mechanism into a logistic distribution, it may be possible to utilize other distributions such as Tobit and probit models (Liu, 2004). In this case, the integral involved in the observed likelihood cannot be explicitly represented, and more unfavorably, this integral may diverge to infinity. Therefore, careful investigation is necessary for the other response mechanism.
To identify the model, the mean structure $\mu(x; \gamma)$ must be more complex than $h(x; \alpha)$ in Corollary 1. The model may be easily identified using basis functions, e.g., Fourier basis that is more complex for estimating the mean structure. This model is advantageous because it enhances the identifiability and enables more complex modeling of the respondents. Additionally, the proposed model can be directly applied to counterfactual analysis or causal inference when there exists nonignorable selection bias.

The proposed FI method can be replaced using multiple imputation (MI), which is a popular method for missing data analysis (Rubin, 1978). Rubin’s variance formula eases the complicated calculation of the asymptotic variance of estimators. However, the congeniality condition requires further discussion to guarantee the applicability of the Rubin’s variance formula, which forms the scope of future work.

References

Appendix

A. Further example

**EXAMPLE 7.** Suppose that \([y \mid x, \delta = 1] \sim \text{Ga}(s, \mu(x; \gamma))\), where \(s\) is the shape parameter, \(\mu(x; \gamma)\) is the mean of this distribution and the density is

\[
\frac{s^s}{\Gamma(s)} \mu^s(x; \gamma)^{y-1} \exp \left\{ - \frac{s}{\mu(x; \gamma)} y \right\}.
\]

This model belongs to the exponential family, with \(\tau = -s\), \(\theta = \mu^{-1}(x; \gamma)\), \(b(\theta) = \log \theta\), \(c(y; \tau) = - \log \{(\tau - \Gamma(-\tau))^{y+1}\}\). The link function \(\theta(\eta) = \exp(-\eta)\) results in density

\[
\frac{s^s}{\Gamma(s)} \exp \left\{ s \left( \sum_{i=1}^L \eta_i(x) \kappa_i \right) \right\} y^{s-1} \exp \left\{ - \frac{s}{\exp \left( \sum_{i=1}^L \eta_i(x) \kappa_i \right)} y \right\}
\]

and \(\gamma = (\kappa^T, s)^T\).

We further check the identification of this model. Function \(\varphi\) in Theorem 1 is

\[
\varphi(\alpha, \beta, \gamma) = b(x; \alpha) + s \log \left\{ s \exp \left( - \sum_{i=1}^L \eta_i(x) \kappa_i \right) + \beta \right\}.
\]

For instance, similar to the binomial case, if \(h(x; \alpha)\) and \(\eta_i(x)\) are polynomials and contain continuous variables, condition (5) holds.

B. Variance estimation of FI

Under some regularity conditions, Riddles et al. (2016) proved that estimator \(\hat{\phi}\) obtained using FI has asymptotic normality:

\[
\sqrt{n} \left( \hat{\phi} - \phi_0 \right) \rightarrow N(0, \Sigma_{\phi}),
\]

where

\[
\Sigma_{\phi} = \mathcal{I}_{22}^{-1} \var \left\{ s_2(\phi_0; \gamma_0) - \mathcal{I}_{21} \mathcal{I}_{11}^{-1} s_1(\gamma_0) \right\} \left( \mathcal{I}_{22}^{-1} \right)^T,
\]

\[
\mathcal{I}_{11} = \var \left\{ s_1(\gamma_0) \right\},
\]

\[
\mathcal{I}_{21} = -E \left\{ (1 - \delta) \left\{ s(\phi_0) - s_0(\phi_0; \gamma_0) \right\} \kappa_1^T(\gamma_0) \right\},
\]

\[
\mathcal{I}_{22} = -E \left\{ (1 - \delta) \tilde{s}_0(\phi_0; \gamma_0) \xi_0^T(x; \phi_0) \right\},
\]

\[
s_1(\gamma) = (\partial / \partial \gamma) \log f(y \mid x, \delta = 1; \gamma), \quad s_2(\phi; \gamma) = \delta s(\phi) + (1 - \delta) \tilde{s}_0(\phi; \gamma), \quad \tilde{s}_0(\phi; \gamma) = E \{ s(\phi) \mid x, \delta = 0; \gamma \}, \quad \xi_0(x; \phi) = E \{ \xi(x, y; \alpha, \beta) \mid x, \delta = 0 \} \]

and \(s(\phi) = S(\alpha, \beta; x, y, \delta)\) is defined in (9). Therefore, the asymptotic variance of \(\phi\) can be estimated as

\[
\frac{1}{n} \mathcal{I}_{22}^{-1} \left\{ \sum_{i=1}^n \mathbf{J}_i \mathbf{J}_i^T + \sum_{i=1}^n \tilde{s}_0^T(\phi_i; x_i) \tilde{s}_0^T(\phi_i; x_i) \right\} \left( \mathcal{I}_{22}^{-1} \right)^T,
\]
where

\[
\mathbf{J}_i = S(\phi; x_i, y_i, \delta_i) - \hat{\mathbf{J}}_{i11} \frac{\partial}{\partial \gamma} \log f(y_i | x_i, \delta = 1; \gamma) \bigg|_{\gamma = \gamma},
\]

\[
\hat{s}_0(\phi; x_i) = \sum_{j, \delta_j = 1} w_{ij}^*(\phi; \gamma) S(\phi; x_i, y_j, \delta_j),
\]

\[
\hat{\mathbf{J}}_{i11} = \frac{1}{n} \sum_{i, \delta_i = 1} \{s_1(\gamma : x_i, y_i) \} \{s_1(\gamma : x_i, y_i)\}^T,
\]

\[
\hat{\mathbf{J}}_{21} = \sum_{i = 1} (1 - \delta_i) \sum_{j, \delta_j = 1} w_{ij}^*(\phi; \gamma) \left\{ S(\phi; x_i, y_j, \delta_j) - \hat{s}_0(\phi; x_i) \right\} s_1(\gamma : x_i, y_j),
\]

\[
\hat{\mathbf{J}}_{22} = \sum_{i = 1} (1 - \delta_i) \hat{s}_0(\phi; x_i) \sum_{j, \delta_j = 1} w_{ij}^*(\phi; \gamma) z^T(x_i, y_j; \phi),
\]

\[
s_1(\gamma : x, y) = \frac{\partial}{\partial \gamma} \log f(y | x, \delta = 1; \gamma), \quad C(y; \gamma) = \sum_{\delta = 1} f(y | x, \delta = 1; \gamma),
\]

\[
w_{ij}^*(\phi; \gamma) = \frac{O(x_i, y_i; \phi) f(y_i | x_j, \delta_j = 1; \gamma) / C(y; \gamma)}{\sum_{\delta = 1} O(x_i, y_i; \phi) f(y_i | x_j, \delta_j = 1; \gamma) / C(y; \gamma)}.
\]

**C. Proofs of Theorems**

First, we prove Theorem 2, which is the most general case. Using Theorem 2, we can prove Theorem 1 for the special case of \( K = 1 \). Theorems 1 and 2 prove Corollary 1 and Corollary 2, respectively.

*(Proof of Theorem 2).* Using Bayes’ theorem, we have

\[
f(y | x, \alpha, \beta, \gamma) P(\delta = 1 | x, y; \alpha, \beta) = \frac{f(y | x, \delta = 1; \gamma)}{\int f(y | x, \delta = 1; \gamma) \{ P(\delta = 1 | x, y; \alpha, \beta) \}^{-1} dy}.
\]

When \((\alpha, \beta, \gamma)\) and \((\alpha', \beta', \gamma')\) provide the same observed likelihood by considering \( y \) on both sides,

\[
\int P(\delta = 1 | x, y; \alpha, \beta) f(y | x, \alpha, \beta, \gamma) dy = \int P(\delta = 1 | x, y; \alpha', \beta') f(y | x, \alpha', \beta', \gamma') dy
\]

\[
\int \frac{f(y | x, \delta = 1; \gamma)}{P(\delta = 1 | x, y; \alpha, \beta)} dy = \int \frac{f(y | x, \delta = 1; \gamma')}{P(\delta = 1 | x, y; \alpha', \beta')} dy.
\]

We further obtain \( f(y | x, \delta = 1; \gamma) = f(y | x, \delta = 1; \gamma') \) using recall before integration. As the distribution \([y | x, \delta = 1]\) is identifiable from this assumption, we can consider the following problem:

\[
\int f(y | x, \delta = 1; \gamma) \frac{1}{P(\delta = 1 | x, y; \alpha', \beta')} dy = (\alpha, \beta) = (\alpha', \beta').
\]

We only show that \( \beta = \beta' \). When \( \beta = \beta' \), we consider the following function.

\[
l(s) = \int f(y | x, \delta = 1; \gamma) \frac{1}{F(s + \beta y)} dy,
\]

where \( F \) denotes logistic distribution. \( l(s) \) is strictly monotonous, because \( F(\cdot) \) is strictly monotonous. We further obtain \( \alpha = \alpha' \) using the following relationship:

\[
l(h(x; \alpha)) = l(h(x; \alpha')) \Rightarrow h(x; \alpha) = h(x; \alpha') \Rightarrow \alpha = \alpha'.
\]
When \(f(y \mid x, \delta = 1; \gamma)\) belongs to an integration of the exponential family and \(P(\delta = 1 \mid x, y, \alpha, \beta)\) is the logistic response mechanism, it can be computed as follows, using the fact that the moment-generating function can be computed explicitly:

\[
\int f(y \mid x, \delta = 1; \gamma) \{P(\delta = 1 \mid x, y, \alpha, \beta)\}^{-1} \, dy
\]

\[
= \int f(y \mid x, \delta = 1; \gamma) \left\{1 + \exp \left(-h(x; \alpha) - \beta y\right)\right\} \, dy
\]

\[
= 1 + \exp \left(-h(x; \alpha)\right) \int \sum_{k=1}^{K} \pi_k \exp \left\{\tau_k (y\theta_k - b(\theta_k)) + c(y; \tau_k)\right\} \cdot \exp (-\beta y) \, dy
\]

\[
= 1 + \exp \left(-h(x; \alpha)\right) \sum_{k=1}^{K} \pi_k \exp (-\tau_k b(\theta_k)) \cdot \exp \left\{\tau_k \left(\theta_k - \frac{\beta}{\alpha}\right)\right\}.
\]

The problem we consider can be transformed as follows:

\[
\int \frac{f(y \mid x, \delta = 1; \gamma)}{P(\delta = 1 \mid x, y, \alpha, \beta)} \, dy = \int \frac{f(y \mid x, \delta = 1; \gamma)}{P(\delta = 1 \mid x, y, \alpha', \beta')} \, dy \exp \{-g(\alpha, \beta, \gamma)\} = \exp \{-g(\alpha', \beta', \gamma)\},
\]

where \(g(\alpha, \beta, \gamma)\) is as defined in Theorem 2. Therefore, the theorem is proven. \(\square\)

(Proof of Theorem 1). Using Theorem 2, we can calculate the following:

\[
g(\alpha, \beta, \gamma) = g(\alpha', \beta', \gamma)
\]

\[
h(x; \alpha) - \left\{-\tau_k (\theta) + \tau_b \left(\theta - \frac{\beta}{\gamma}\right)\right\} = h(x; \alpha') - \left\{-\tau_k (\theta) + \tau_b \left(\theta - \frac{\beta}{\gamma}\right)\right\}
\]

\[
h(x; \alpha) - \tau_b \left(\theta - \frac{\beta}{\gamma}\right) = h(x; \alpha') - \tau_b \left(\theta - \frac{\beta'}{\gamma}\right).
\]

Hence, we prove the theorem. \(\square\)

(Proof of Theorem 3). We further consider two functions \(g\) in Corollary 2, with different parameters:

Model 1 : \(\sum_{i=1}^{K} \pi_i \exp \left\{-h(x; \alpha) - \beta \mu_i(x; \kappa_i) + \frac{1}{2} \beta^2 \sigma_i^2\right\}\)

Model 2 : \(\sum_{i=1}^{K} \pi_i \exp \left\{-h(x; \alpha') - \beta' \mu_i(x; \kappa_i) + \frac{1}{2} \beta'^2 \sigma_i^2\right\}\)

According to condition (C2) and Lemma 1, there exists a \(K \times K\) permutation matrix \(P\), such that

\[
P \beta \mu^M(x) = \beta' \mu^M(x), \quad (10)
\]

where \(\mu^M(x) = (\mu^M_1(x; \kappa_1), \ldots, \mu^M_K(x; \kappa_K))^T\).

\[
P^n \mu^M(x) = P^{n-1} \cdot P \mu^M(x) = P^{n-1} \cdot \frac{\beta'}{\beta} \mu^M(x) = \cdots = \left(\frac{\beta'}{\beta}\right)^n \mu^M(x)
\]

Note that there exists \(n \in \mathbb{N}\) such that \(P^n = I\), because \(P\) is a permutation matrix. Therefore, we find that \(n \in \mathbb{N}\) exists such that \((\beta'/\beta)^n = 1\), which means that \(\beta = \beta'\) or \(\beta = -\beta'\). When condition (C3) holds, we obtain \(\beta = \beta'\); therefore, this model is identifiable. When \(\beta = -\beta'\), Equation (10) is \(P \mu^M(x) = -\mu^M(x)\), which means that (C4) is not satisfied. Therefore, this model is identifiable when (C4) holds. \(\square\)
(Proof of Theorem 4). We consider the same two models as in the proof of Theorem 3.

Model 1: \[ \sum_{i=1}^{K} \pi_i \exp \left\{ \left( -\alpha_0 - \beta \kappa_0 + \frac{1}{2} \beta^2 \sigma_1^2 \right) - (\alpha_1 + \beta \kappa_{i1}) x \right\} \]

Model 2: \[ \sum_{i=1}^{K} \pi_i \exp \left\{ \left( -\alpha_0' - \beta' \kappa_0 + \frac{1}{2} \beta'^2 \sigma_1^2 \right) - (\alpha_1' + \beta' \kappa_{i1}) x \right\}. \]

We further examine the coefficients of \( x \). We assume that Models 1 and 2 are equal. We then obtain the following using the permutation matrix \( P \) because of linear independence for the exponential of the polynomial.

\[ P (\alpha_1 1_K + \beta \kappa) = \alpha_1' 1_K + \beta' \kappa. \]

where \( \kappa = (\kappa_{11}, \ldots, \kappa_{1K})^T \). Note that \( 1_K \) is one of eigenvectors of a permutation matrix, and the eigenvalue is 1. We calculate the following:

\[ P \kappa = \left( \frac{\alpha_1' - \alpha_1}{\beta} \right) 1_K + \frac{\beta'}{\beta} \kappa. \]

We can calculate

\[ P^2 \kappa = P \left\{ \left( \frac{\alpha_1' - \alpha_1}{\beta} \right) 1_K + \frac{\beta'}{\beta} \kappa \right\} = \left( \frac{\alpha_1' - \alpha_1}{\beta} \right) 1_K + \frac{\beta'}{\beta} P \kappa \]

\[ = \left( 1 + \frac{\beta'}{\beta} \right) \left( \frac{\alpha_1' - \alpha_1}{\beta} \right) 1_K + \left( \frac{\beta'}{\beta} \right)^2 \kappa. \]

Note that there exists \( n \in \mathbb{N} \) such that \( P^n = I \), because \( P \) is a permutation matrix. Therefore, we obtain the following by calculating \( P^2 \kappa \):

\[ \kappa = P^n \kappa \]

\[ = \left\{ 1 + \frac{\beta'}{\beta} + \cdots + \left( \frac{\beta'}{\beta} \right)^{n-1} \right\} \frac{\alpha_1' - \alpha_1}{\beta} 1_K + \left( \frac{\beta'}{\beta} \right)^n \kappa. \]

Hence, we obtain the following equation:

\[ \left\{ 1 - \left( \frac{\beta'}{\beta} \right)^n \right\} \kappa = \left\{ 1 + \frac{\beta'}{\beta} + \cdots + \left( \frac{\beta'}{\beta} \right)^{n-1} \right\} \frac{\alpha_1' - \alpha_1}{\beta} 1_K \]

If \( \beta \neq \beta' \) holds, and the sign of \( \beta \) is known, we have \( \kappa_1 = C 1_K \), where \( C \) is constant. However, this result is inconsistent with \( \kappa_{i1} \neq \kappa_{j1} \) (\( i \neq j \)). Therefore, we obtain \( \beta = \beta' \).

We further show that \( \beta = \beta' \) in the second condition. Based on the above argument, we use \( \beta \neq \beta' \Rightarrow \beta = -\beta' \) and obtain:

\[ P \kappa = \left( \frac{\alpha_1' - \alpha_1}{\beta} \right) 1_K + \frac{\beta'}{\beta} \kappa = \left( \frac{\alpha_1' - \alpha_1}{\beta} \right) 1_K - \kappa. \]

However, this is inconsistent with the second condition. Therefore, we find that \( \beta = \beta' \).

(Proof of Theorem 5). We consider the same two models as in the proof of Theorem 3.

Model 1: \[ \sum_{i=1}^{2} \pi_i \exp \left\{ \left( -\alpha_0 - \beta \kappa_0 + \frac{1}{2} \beta^2 \sigma_1^2 \right) - (\alpha_1 + \beta \kappa_{i1}) x \right\}. \]

Model 2: \[ \sum_{i=1}^{2} \pi_i \exp \left\{ \left( -\alpha_0' - \beta' \kappa_0 + \frac{1}{2} \beta'^2 \sigma_1^2 \right) - (\alpha_1' + \beta' \kappa_{i1}) x \right\}. \]
First, we show that equalisation of each component does not occur. In other words, if there exists two non-identifiable models, Models 1 and 2, the components $k = 1$ of Model 1 and $k = 2$ of Model 2 are equal.

Assuming that components $k = 1$ of Model 1 and $k = 1$ of Model 2 are equal, we compare the coefficient of $x$,

$$
\alpha_1 + \beta \kappa_{11} = \alpha'_1 + \beta' \kappa_{11},
\alpha_1 + \beta \kappa_{12} = \alpha'_1 + \beta' \kappa_{12}.
$$

$\beta \neq \beta'$ because Models 1 and 2 are not identifiable. Therefore, we obtain

$$
\kappa_{11} = \frac{\alpha_1 - \alpha'_1}{\beta' - \beta} = \kappa_{12}.
$$

This contradicts condition 1; therefore, the equalisation of each component does not occur. Moreover, the following holds:

$$
\alpha_1 + \beta \kappa_{11} = \alpha'_1 + \beta' \kappa_{12};
\alpha_1 + \beta \kappa_{12} = \alpha'_1 + \beta' \kappa_{11},
$$

and we can calculate

$$
\beta (\kappa_{11} - \kappa_{12}) = \beta' (\kappa_{12} - \kappa_{11}).
$$

This implies that $\beta = -\beta'$ because of $\kappa_{11} \neq \kappa_{12}$. We further compare the constant parts. If the two models are not identifiable, then:

$$
-\alpha_0 - \beta \kappa_{01} + \frac{1}{2} \beta^2 \sigma^2_1 + \log \pi_1 = -\alpha'_0 - \beta' \kappa_{02} + \frac{1}{2} \beta'^2 \sigma^2_2 + \log \pi_2
$$

$$
-\alpha_0 - \beta \kappa_{02} + \frac{1}{2} \beta^2 \sigma^2_2 + \log \pi_2 = -\alpha'_0 - \beta' \kappa_{01} + \frac{1}{2} \beta'^2 \sigma^2_1 + \log \pi_1.
$$

because $\beta = -\beta'$, we can calculate the

$$
\frac{1}{2} \beta^2 \sigma^2_1 + \log \pi_1 = \frac{1}{2} \beta^2 \sigma^2_2 + \log \pi_2.
$$

In other words, we consider contraposition, if for all $\beta \in \mathbb{R}$,

$$
\frac{1}{2} \beta^2 \sigma^2_1 + \log \pi_1 \neq \frac{1}{2} \beta^2 \sigma^2_2 + \log \pi_2.
$$

The models were then identifiable. Hence, we obtain

$$
\beta^2 (\sigma^2_1 - \sigma^2_2) \neq 2 (\log \pi_2 - \log \pi_1).
$$

The above relationship holds because of Conditions 2 and 3.

The following lemma shows the linear independence of exponentials of multivariate polynomials. This result plays an important role in deriving the identification condition for a normal mixture. A related proof exists on the Stack Exchange website, which we provide here in a more extended form.

**Lemma 1.** Let $\mathbf{x}$ be the $p$-dimensional vector $(x_1, \ldots, x_p)^\top$, $P_1(\mathbf{x}), \ldots, P_n(\mathbf{x})$ be distinct multivariate polynomials without a constant term, $R_1(\mathbf{x}), \ldots, R_n(\mathbf{x})$ be a rational function of multivariate polynomials, and the domain of all these functions is the subset of the Euclidean space $\mathbb{R}^p$ which contains an interior point. Then, the following result holds:

$$
R_1(\mathbf{x})e^{P_1(\mathbf{x})} + \cdots + R_n(\mathbf{x})e^{P_n(\mathbf{x})} = 0 \Rightarrow R_1(\mathbf{x}) = \cdots = R_n(\mathbf{x}) = 0.
$$
Note that Lemma 1 implies the linear independence of exponentials of multivariate polynomials when the functions $R_1(x), \ldots, R_n(x)$ are constant.

(Proof of Lemma 1). We prove this through a mathematical induction. The case where $n = 1$ is trivial. We further assume that the case $n = k - 1$ holds. Let

$$R_1(x)e^{P_1(x)} + \cdots + R_k(x)e^{P_k(x)} = 0,$$

where $P_1(x), \ldots, P_k(x)$ are distinct polynomials without a constant term and $R_1(x), \ldots, R_k(x)$ are rational functions. If $R_k(x) \neq 0$, it follows that

$$\frac{R_1(x)}{R_k(x)}e^{P_1(x) - P_k(x)} + \cdots + \frac{R_{k-1}(x)}{R_k(x)}e^{P_{k-1}(x) - P_k(x)} + 1 = 0.$$

Both sides are differentiable at the interior point of the domain of all functions. Therefore, we obtain

$$\sum_{i=1}^{k-1} \left\{ \frac{d}{dx_i} \left( \frac{R_i(x)}{R_k(x)} \right) + \frac{R_i(x)}{R_k(x)} \cdot \frac{d}{dx_i} (P_i(x) - P_k(x)) \right\} e^{P_i(x) - P_k(x)} = 0.$$

Because $P_1 - P_k, \ldots, P_{k-1} - P_k$ are distinct multivariate polynomials without a constant term, the assumption of the $n = k - 1$ case yields

$$\left\{ \frac{d}{dx_i} \left( \frac{R_i(x)}{R_k(x)} \right) + \frac{R_i(x)}{R_k(x)} \cdot \frac{d}{dx_i} (P_i(x) - P_k(x)) \right\} e^{P_i(x) - P_k(x)} = 0,$$

where $i = 1, \ldots, k - 1$. Considering the integrals of both sides, we obtain

$$\frac{R_i(x)}{R_k(x)}e^{P_i(x) - P_k(x)} = C_i(x_1, \ldots, x_{i-1}, x_{i+1}, \ldots, x_p),$$

where $l = 1, \ldots, p$. The left-hand side is constant, because it does not depend on $l$. This denotes $C_i$. If $C_i \neq 0$, $R_i(x)/R_k(x)$ and $P_i(x) - P_k(x)$ are constant. This contradicts the fact that $P_1(x), \ldots, P_k(x)$ are distinct polynomials, without a constant term. If $C_i = 0$, we obtain the following contradictory equation.

$$\frac{R_1(x)}{R_k(x)}e^{P_1(x) - P_k(x)} + \cdots + \frac{R_{k-1}(x)}{R_k(x)}e^{P_{k-1}(x) - P_k(x)} + 1 = 0$$

$$1 = 0.$$

Hence, we obtain $R_k(x) = 0$. It follows

$$R_1(x)e^{P_1(x)} + \cdots + R_{k-1}(x)e^{P_{k-1}(x)} = 0;$$

we further obtain $R_1(x) = \cdots = R_{k-1}(x) = 0$ based on the assumption of the $n = k - 1$ case. Therefore, the lemma is proven.
