PAC-Bayes training for neural networks: sparsity and uncertainty quantification

Maximilian F. Steffen and Mathias Trabs

Abstract
We study the Gibbs posterior distribution from PAC-Bayes theory for sparse deep neural nets in a nonparametric regression setting. To access the posterior distribution, an efficient MCMC algorithm based on backpropagation is constructed. The training yields a Bayesian neural network with a joint distribution on the network parameters. Using a mixture over uniform priors on sparse sets of networks weights, we prove an oracle inequality which shows that the method adapts to the unknown regularity and hierarchical structure of the regression function. Studying the Gibbs posterior distribution from a frequentist Bayesian perspective, we analyze the diameter and show high coverage probability of the resulting credible sets. The method is illustrated in a simulation example.

Keywords: Adaptive nonparametric estimation, Bayesian neural network, optimal contraction rate, credible sets, oracle inequality, MCMC by backpropagation

1 Introduction
Driven by the enormous success of neural networks in a broad spectrum of machine learning applications, see Goodfellow et al. (2016) and Schmidhuber (2015) for an introduction, the theoretical understanding of network based methods is a dynamic and flourishing research area at the intersection of mathematical statistics, optimization and approximation theory. In addition to theoretical guarantees uncertainty quantification is an important and challenging problem for neural networks. This has motivated the introduction of Bayesian neural networks, where for each network weight a distribution is learned, see Graves (2011) and Blundell et al. (2015) and numerous subsequent articles. Considering a (nonparametric) regression problem, we introduce a training approach, which we call MCMC by backprop, for a Bayesian neural network which allows for both, an adaptive and optimal bound for the prediction risk as well as credible sets with a verified high coverage probability of the unknown regression function.

While early theoretical foundations for neural nets are summarized by Anthony & Bartlett (1999), the excellent approximation properties of deep neural nets, especially with the ReLU activation function, have been discovered in the last years, see e.g. Yarotsky (2017), the review paper DeVore et al. (2021) and Boleskei et al. (2019) for sparse deep neural networks. In addition to these approximation properties, an essential explanation of the empirical capabilities of neural networks has recently been given by Schmidt-Hieber (2020) as well as Bauer & Kohler (2019). While classical regression methods suffer from the curse of dimensionality, sparse neural network estimators can profit from a hierarchical structure of the regression function and a possibly much smaller intrinsic dimension. In particular, Schmidt-Hieber (2020) has analyzed sparse deep neural networks with ReLU activation function which is the network class considered in this work. To achieve a sparse neural network, a standard approach is to use penalized empirical risk minimization which has been analyzed for neural nets by Taheri et al. (2021).

Instead of penalized empirical risk minimization, we train a neural network by learning the Gibbs posterior distribution from PAC-Bayes theory. The resulting Bayesian neural network reveals two advantages: First, a PAC-Bayes trained sparse network satisfies an oracle inequality which implies an
adaptive version of the upper bound by Schmidt-Hieber (2020), i.e., the network estimator achieves this upper bound without prior knowledge of the hierarchical structure and the regularity of the regression function. Second, as mentioned above, the Bayes methodology comes with the possibility of uncertainty quantification. Defining credible sets as $L^2$-balls with high probability under the posterior distribution, we show that these balls indeed contain the unknown regression function with high probability.

The PAC-Bayes approach goes back to Shawe-Taylor & Williamson (1997) and McAllester (1999a,b). In a quite general setting it is possible to derive upper bounds for the prediction error either in terms of the empirical risk or in terms of an oracle inequality. We refer to the review papers by Guedj (2019) and [Alquier (2021)]. Empirical PAC-Bayes bounds are intensively studied for (deep) neural nets, see Dziugaite & Roy (2017), Pérez-Ortiz et al. (2021) and further references in [Alquier (2021), Section 3.3). PAC-Bayes oracle inequalities are less well studied. An exception is Chérief-Abdellatif (2020), who has proved a (non-adaptive) oracle inequality for the variational approximation of the PAC-Bayes procedure based on the theory by Catoni (2007), and Tinsi & Dalalyan (2021) who have used the PAC-Bayes bound for an aggregation of (shallow) neural networks.

Our analysis of the Bayesian procedure from a frequentist point of view embeds into the nonparametric Bayesian inference, see Ghosal & van der Vaart (2017). Coverage of credible sets has been studied, for instance, by Szabó et al. (2015) and Rousseau & Szabó (2020) and based on the Bernstein-von Mises theorem in Castillo & Nickl (2014) among others. While contraction rates for Bayes neural networks have been studied by Polson & Rockova (2018) and Chérief-Abdellatif (2020), the theoretical properties of credible sets are not well understood so far. In view of the complex dependence between the network weights and the estimated function, there are also similarities to the analysis of Bayes procedures for inverse problems, see Stuart (2010) and, e.g., Knapik et al. (2011) as well as Nickl (2020) for uncertainty quantification, although we do not have to invert the forward operator from the network weights to the regression function.

In order to apply the PAC-Bayes approach to training neural networks, we replace the typical gradient based optimization of the empirical risk, by a Markov chain Monte Carlo (MCMC) method. In the construction of the Markov chain, we can exploit the well-established and efficient gradient descent algorithms. More precisely, MCMC by backprop relies on a Metropolis-Hastings algorithm where the proposal density is centred around a gradient descent step. This yields an efficient MCMC algorithm whose computational costs are comparable to a gradient based method. The MCMC approach is different to the majority of literature on Bayes neural networks which mainly focus on variational Bayesian inference, see Blei et al. (2017) for a review on variational inference and Graves (2011) and Blundell et al. (2015) for early applications to neural networks. To adapt to sparsity, we can choose a prior that prefers networks with sparse weights.

It should be noted that due to the non-convex dependence on the network weights, the computational analysis of such an MCMC algorithm is as challenging as the convergence analysis of gradient based methods towards a global risk minimizer. Motivated by Bayesian inverse problems, there have been some recent investigations in this direction by Nickl & Wang (2020).

The paper is organized as follows: In Section 2, we introduce the PAC-Bayes training method and discuss its implementation. In Section 3, we state the oracle inequality providing theoretical guarantees for the proposed method and we investigate credible sets. A numerical illustration of the method is given in Section 4. All proofs have been postponed to Section 5 and some further details on algorithmic aspects are contained in Section 6.

2 PAC-Bayes training

We consider a training sample $\mathcal{D}_n = (X_i, Y_i)_{i=1,...,n} \subseteq \mathbb{R}^p \times \mathbb{R}$ given by $n \in \mathbb{N}$ i.i.d. copies of generic random variables $(X, Y) \in \mathbb{R}^p \times \mathbb{R}$ on some probability space and the aim to estimate the regression function $f: \mathbb{R}^p \rightarrow \mathbb{R}$ given by $Y = f(X) + \varepsilon$ with observation error $\varepsilon$ satisfying $E[\varepsilon \mid X] = 0$ a.s. Equivalently, $f(X) = E[Y \mid X]$ a.s. For any estimator $\hat{f}$, the prediction risk and its empirical counterpart
are given by

\[ R(\hat{f}) := \mathbb{E}_f [(Y - \hat{f}(X))^2] \quad \text{and} \quad R_n(\hat{f}) = \frac{1}{n} \sum_{i=1}^{n} (Y_i - \hat{f}(X_i))^2, \] (2.1)

respectively. The accuracy of the estimation procedure will be quantified in terms of the excess risk

\[ \mathcal{E}(\hat{f}) := R(\hat{f}) - R(f) = \mathbb{E}_f ([\hat{f}(X) - f(X)]^2) = \| \hat{f} - f \|_{L_2(P_X)}^2. \]

In the following we first introduce the considered class of sparse neural networks. Afterwards, we introduce and discuss the Bayesian training method. Throughout, \( |x|_q \) denotes the \( \ell_q \)-norm of a vector \( x \in \mathbb{R}^p, q \in [1, \infty] \). In particular, \( | \cdot |_2 \) is the Euclidean norm. For a set \( I \), the cardinality is denoted by \( |I| \).

### 2.1 Sparse neural networks

We consider a feedforward multilayer perceptron with \( L \in \mathbb{N} \) hidden layers and widths vector \( \vec{p} = (p_0, p_1, \ldots, p_{L+1}) \in \mathbb{N}^{L+2} \) where \( p_0 = p \) and \( p_{L+1} = 1 \). The rectified linear unit (ReLU) \( \sigma(x) := \max\{x, 0\}, x \in \mathbb{R} \), is used as activation function. We write \( \sigma_b x := (\sigma(x_i + b_i))_{i=1, \ldots, d} \) for vectors \( x, b \in \mathbb{R}^d \).

With this notation we can represent a neural network with architecture \((L, \vec{p})\) as

\[ g_\theta(x) := W^{(L+1)} \sigma_b^{(L+2)} \cdots W^{(2)} \sigma_b^{(2)} W^{(1)} x, \quad x \in \mathbb{R}^p, \]

for weight matrices \( W^{(l)} \in \mathbb{R}^{p_l \times p_{l-1}}, l = 1, \ldots, L + 1 \) and shift vectors \( b^{(l)} \in \mathbb{R}^{p_l}, l = 1, \ldots, L \). The total number of network parameters is

\[ |\vec{\theta}| := \sum_{l=1}^{L+1} p_l p_{l-1} + \sum_{l=1}^{L} p_l. \]

Using some fixed bijection between \((X_{l=1}^{L+1} \mathbb{R}^{p_l \times p_{l-1}}) \times (X_{l=1}^{L} \mathbb{R}^{p_l})\) and \( \mathbb{R}^{|\vec{\theta}|} \), all entries of \( W^{(1)}, \ldots, W^{(L+1)} \) and \( b^{(1)}, \ldots, b^{(L)} \) are collected in one large vector \( \vartheta \in \mathbb{R}^{|\vec{\theta}|} \). A possibly more intuitive layer-wise representation of \( g_\theta \) is given by

\[ \begin{align*}
    x^{(0)} &:= x \in \mathbb{R}^p, \\
    x^{(l)} &:= \sigma(W^{(l)} x^{(l-1)} + b^{(l)}), \quad l = 1, \ldots, L, \\
    g_\theta(x) &:= x^{(L+1)} := W^{(L+1)} x^{(L)},
\end{align*} \] (2.2)

where the activation function is applied coordinate-wise. We denote the class of all such functions \( g_\theta \) by \( \mathcal{G}(L, \vec{p}) \). A network is sparse, or more precisely connection sparse, if many weights in the network are zero and thus some links between nodes are inactive. For some active set \( I \subseteq \{1, \ldots, |\vec{\theta}|\} \), the corresponding class of sparse networks is defined by

\[ \mathcal{G}(L, \vec{p}, I) := \{ g_\theta \in \mathcal{G}(L, \vec{p}) : \vartheta_i = 0 \text{ if } i \notin I \}. \]

For some \( C \geq 1 \), we also introduce the class of clipped networks

\[ \mathcal{F}(L, \vec{p}, C) := \{ f_\theta := (-C) \vee (g_\theta \wedge C) \mid g_\theta \in \mathcal{G}(L, \vec{p}) \} \]

and similarly we denote clipped networks with active set \( I \) by \( \mathcal{F}(L, \vec{p}, I, C) \). We abbreviate \( R(\vartheta) = R(f_\theta) \) and \( R_n(\vartheta) = R_n(f_\theta) \).
2.2 Prior and posterior distribution

In order to adopt the PAC-Bayes approach to neural networks, we first choose a prior on the weights in the network class $G(L, \vec{p})$. For a given active set $I$ the prior $\Pi_I$ on the parameter set of the class $G(L, \vec{p}, I)$ is defined as the uniform distribution on

$$S_I := \{ \vartheta \in [-B, B]^{|\vec{p}|} \mid \vartheta_i = 0 \text{ if } i \notin I \}$$

(2.3)

for some $B \geq 1$. In the special case $I^\ast := \{1, \ldots, |\vec{p}|\}$ we obtain a prior $\Pi^\ast := \Pi_{I^\ast}$ on the non-sparse network class $G(L, \vec{p})$. To allow for a data-driven choice of the active set, we define the prior $\Pi$ as a mixture of the uniform priors $\Pi_I$:

$$\Pi := \sum_{i=1}^{|\vec{p}|} s^{-i} \sum_{I \subseteq \{1, \ldots, |\vec{p}|\}, |I| = i} \left( \frac{|\vec{p}|}{i} \right)^{-1} \Pi_I / C_s \quad \text{with} \quad C_s := (1 - s^{-|\vec{p}|})/(s - 1)$$

(2.4)

where $s \geq 2$ is a sparsity parameter. A larger $s$ leads to a stronger preference of sparse networks. The prior $\Pi$ can be understood as a hierarchical prior, where we first draw a geometrically distributed sparsity $i$, given $i$ we uniformly choose an active set $I \subseteq \{1, \ldots, |\vec{p}|\}$ with $|I| = i$ and on $I$ the uniform prior $\Pi_I$ is applied.

Based on $\Pi$, the Gibbs posterior probability distribution $\Pi_\lambda(\cdot \mid \mathcal{D}_n)$ is defined via

$$\Pi_\lambda(d\vartheta \mid \mathcal{D}_n) \propto \exp(-\lambda R_n(\vartheta))\Pi(d\vartheta)$$

(2.5)

with the so-called temperature parameter $\lambda > 0$ and empirical prediction risk from (2.1). While (2.5) coincides with the classical Bayesian posterior distribution if $Y_i = f_\vartheta(X_i) + \epsilon_i$ with i.i.d. $\epsilon_i \sim \text{N}(0, \frac{1}{n})$, the so-called tempered likelihood $\exp(-\lambda R_n(\vartheta))$ serves as a proxy for the unknown distribution of the observations given $\vartheta$. As we will see, the method is indeed applicable under quite general assumptions on the regression model. The Gibbs posterior distribution weights each $\vartheta$ based on its empirical performance on the data, where the temperature parameter $\lambda$ determines the impact $R_n(\vartheta)$ in comparison to the prior beliefs.

An estimator for $f$ can be obtained by drawing from the posterior distribution, i.e.,

$$\hat{f}_\lambda := f_{\hat{\vartheta}_\lambda} \quad \text{for} \quad \hat{\vartheta}_\lambda \sim \Pi_\lambda(\cdot \mid \mathcal{D}_n)$$

(2.6)

or in the form of the posterior mean

$$\hat{f}_\lambda := \mathbb{E}_f[f_{\hat{\vartheta}_\lambda} \mid \mathcal{D}_n] = \int f_\vartheta \Pi_\lambda(d\vartheta \mid \mathcal{D}_n).$$

(2.7)

Another popular approach is to use the maximum a posteriori (MAP) estimator, but we will focus on the previous two estimators.

2.3 MCMC algorithm

Since the normalizing constant of the posterior distribution is unknown, the posterior distribution itself is not accessible in practice. Popular Bayesian networks rely on a variational Bayes approach, cf. [Blei et al. (2017)], and approximate the posterior by some easier distribution. For instance, the Bayes by backprop method by [Blundell et al. (2015)] uses independent normal distributions for the weights such that the training of the Bayesian network reduces to the calibration of the means and variances for all weights. In contrast, the classical approach in Bayesian statistics is to sample $\vartheta$ by constructing a Markov-chain $(\vartheta^{(k)})_{k \in \mathbb{N}_0}$ with stationary distribution $\Pi_\lambda(\cdot \mid \mathcal{D}_n)$ with a Markov chain Monte Carlo (MCMC) method, see [Robert & Casella (2004)]. In particular, the Metropolis-Hastings algorithm does not require the normalizing constant of the target distribution. The MCMC approach aims for the exact posterior distribution and has been successfully applied for complex models like nonlinear inverse problems,
which motivates the construction of the proposed MCMC by backprop algorithm to learn the Gibbs posterior distribution for neural networks.

For ease of presentation, we will discuss this PAC-Bayes training approach for the prior \( \Pi^\star \) on the non-sparse network class \( \mathcal{G}(L, p) \), i.e. \( \Pi^\star \) is the uniform distribution on \([-B, B]^{|\theta}|^p\). The corresponding posterior distribution is denoted by \( \Pi^\star(\theta|\mathcal{D}_n) \propto \exp(-\lambda R_n(\theta))\Pi^\star(\theta) \).

Applying the generic Metropolis-Hastings algorithm to \( \Pi^\star(\theta|\mathcal{D}_n) \) and taking into account that the prior \( \Pi^\star \) is uniform, we obtain the following iterative method: Starting with some initial choice \( \vartheta(0) \in \mathbb{R}^{|\theta}|^p \), we successively generate \( \vartheta(k+1) \) given \( \vartheta(k) \), \( k \in \mathbb{N}_0 \), by

\[
\vartheta(k+1) = \begin{cases} \tau(k) & \text{with probability } \alpha(\tau(k), \vartheta(k)) \\ \vartheta(k) & \text{with probability } 1 - \alpha(\tau(k), \vartheta(k)) \end{cases},
\]

where \( \tau(k) \) is a random variable drawn from some conditional proposal density \( q(\cdot | \vartheta(k)) \) and the acceptance probability is given by

\[
\alpha(\tau(k), \vartheta(k)) = \min\left\{ 1, \exp\left( -\lambda R_n(\tau(k)) + \lambda R_n(\vartheta(k)) \right) \mathbb{1}_{[-B, B]}(\vartheta(k)) \frac{q(\tau(k) | \vartheta(k))}{q(\vartheta(k) | \tau(k))} \right\}.
\]

The success of the PAC-Bayes training fundamentally depends on the choice of the proposal distribution. In the construction of \( q(\tau|\vartheta) \), we exploit the well-known gradient approach for an empirical risk minimizer

\[
\vartheta^* \in \arg \min_{\vartheta} R_n(\vartheta)
\]

with the empirical risk \( R_n(\vartheta) = R_n(f_\vartheta) \) from \([2.1]\). The gradient \( \nabla_\vartheta R_n(\vartheta) \) of \( R_n(\vartheta) \) with respect to \( \vartheta \) can be computed efficiently using backpropagation. The gradient descent method commonly used to train neural networks would suggest to tweak a given \( \vartheta(k) \) in the direction of the gradient, that is

\[
\tilde{\vartheta}(k+1) = \vartheta(k) - \gamma \nabla_\vartheta R_n(\vartheta(k))
\]

with a learning rate \( \gamma > 0 \). Therefore, we propose a normal distribution around \( \tilde{\vartheta}(k+1) \) with some standard deviation \( \sigma > 0 \). This standard deviation should not be too large as otherwise the acceptance probability might be too small. As a result the proposal would rarely be accepted, the chain might not be sufficiently randomized and the convergence to the invariant target distribution would be too slow in practice. On the other hand, \( \sigma \) should not be smaller than the shift \( \gamma \nabla_\vartheta R_n(\vartheta(k)) \) in the mean, since otherwise \( q(\vartheta(k) | \tau(k)) \) might be too small. Our practical experiments revealed that \( \sigma = \gamma \) is a quite robust choice which we will use throughout, but in principle \( \sigma \) can be used as a further tuning parameter if necessary. Therefore, the probability density \( q(\cdot | \vartheta) \) of the proposal distribution is given by the density

\[
q(\tau | \vartheta) = \frac{1}{(2\pi \sigma^2)^{d/2}} \exp\left( -\frac{\tau^2}{2\sigma^2} + \tau - \vartheta + \gamma \nabla_\vartheta R_n(\vartheta) \right) , \quad (2.8)
\]

The above ensures that \( (\vartheta(k))_{k \in \mathbb{N}_0} \) is a Markov chain with invariant distribution \( \Pi^\star(\cdot | \mathcal{D}_n) \). The convergence to the invariant distribution follows from \( \text{Roberts & Tweedie (1996 Theorem 2.2)} \).

To calculate the estimators \( \hat{f}_\lambda \) and \( \tilde{f}_\lambda \) from \([2.6]\) and \([2.7]\) respectively, one chooses a burn-in time \( b \in \mathbb{N} \) to let the distribution of the Markov chain stabilize at its invariant distribution and then sets

\[
\hat{f}_\lambda := f_{\vartheta(b+c)} \quad \text{and} \quad \tilde{f}_\lambda := \frac{1}{m} \sum_{k=1}^{m} f_{\vartheta(b+c(k))} .
\]

A sufficiently large gap length \( c \in \mathbb{N} \) ensures the necessary variability and an approximate independence between \( f_{\vartheta(b+c(k))} \) and \( f_{\vartheta(b+c(k+1))} \), whereas \( m \in \mathbb{N} \) has to be large enough for a good approximation of the expectation by the empirical mean. The MCMC method is summarized in \( \text{Algorithm 1} \). The implementation omits the restriction of the proposed network weights to \([-B, B]^{|\vartheta}|^p\) and the clipping of the resulting of networks at \( C \), since these modifications are practically negligible for sufficiently large constants \( B \) and \( C \).
which is not accessible to the practitioner because from a possibly large number of necessary iterations due to the rejection with probability to the training of a non-Bayesian network, the additional computational price of Algorithm 1 only comes based methods such as mini-batch stochastic gradient descent or Adam (Kingma & Ba, 2014). Compared

A solution to the minimization problem in (3.1) always exists since \( \mathcal{S}_T \) is compact and \( \vartheta \mapsto R(f_\vartheta) \) is

**Algorithm 1** MCMC by backprop algorithm for training a fully connected neural network.

```
Input: temperature \( \lambda > 0 \), learning rate \( \gamma > 0 \), burn-in \( b \in \mathbb{N} \), gap length \( c \in \mathbb{N} \), number of draws \( m \in \mathbb{N} \).

1. Randomly draw initialization parameter \( \vartheta^{(0)} \in \mathbb{R}^{\|\vartheta\|} \).
2. Calculate \( R_n(\vartheta^{(0)}) \) and \( \nabla_{\vartheta} R_n(\vartheta^{(0)}) \) with backpropagation.
3. For \( k = 0, \ldots, b + cm - 1 \) do:
   (a) Draw \( \tau^{(k)} \sim N(\vartheta^{(k)} - \nabla_{\vartheta} R_n(\vartheta^{(k)}), \gamma^2) \) and calculate \( R_n(\tau^{(k)}) \) and \( \nabla_{\vartheta} R_n(\tau^{(k)}) \) with backpropagation.
   (b) Calculate acceptance probability
   \[
   \alpha(\tau^{(k)}, \vartheta^{(k)}) = \exp \left( -\lambda R_n(\tau^{(k)}) - \frac{1}{2\gamma^2} \|\vartheta^{(k)} - \tau^{(k)} + \nabla_{\vartheta} R_n(\tau^{(k)})\|_2^2 \right.
   \]
   \[
   + \lambda R_n(\vartheta^{(k)}) + \frac{1}{2\gamma^2} \|\tau - \vartheta + \nabla_{\vartheta} R_n(\vartheta)\|_2^2 \right) + 1.
   \]
   (c) Draw \( u \sim U([0, 1]) \). If \( u \leq \alpha(\tau^{(k)}, \vartheta^{(k)}) \), then set \( \vartheta^{(k+1)} = \tau^{(k)} \), \( R_n(\vartheta^{(k+1)}) = R_n(\tau^{(k)}) \), \( \nabla_{\vartheta} R_n(\vartheta^{(k+1)}) = \nabla_{\vartheta} R_n(\tau^{(k)}) \), else set \( \vartheta^{(k+1)} = \vartheta^{(k)} \), \( R_n(\vartheta^{(k+1)}) = R_n(\vartheta^{(k)}) \), \( \nabla_{\vartheta} R_n(\vartheta^{(k+1)}) = \nabla_{\vartheta} R_n(\vartheta^{(k)}) \).

Output: \( \hat{f}_\lambda = f_{\vartheta^{(b)}} , \hat{f}_\lambda = \frac{1}{m} \sum_{k=0}^{m-1} f_{\vartheta^{(k+b)}} \).
```

Note that the gradient has to be calculated only once in each MCMC iteration. While we use the standard gradient, the calculation of \( \nabla_{\vartheta} R_n \) could be realized and combined with state-of-art gradient based methods such as mini-batch stochastic gradient descent or Adam (Kingma & Ba, 2014). Compared to the training of a non-Bayesian network, the additional computational price of Algorithm 1 only comes from a possibly large number of necessary iterations due to the rejection with probability \( 1 - \alpha(\tau^{(k)}, \vartheta^{(k)}) \).

In order to extend the Metropolis-Hastings algorithm from the full prior \( \Pi^* \) to the mixing prior \( \Pi \) from \([2.4]\) we have to take into account the hierarchical structure of \( \Pi \). Hence, we use the reversible-jump Markov chain Monte Carlo (RJMCMC) algorithm first proposed by Green (1995). In the context of a PAC-Bayes method it has been discussed in Gučci (2019). In particular, the RJMCMC algorithm has been successfully applied by Alquier & Biau (2013) in a high-dimensional regression setting. Some further details on the PAC-Bayes training of neural networks with the RJMCMC algorithm are given in Section 6 and the full implementation in Python 3 is available on GitLab.

### 3 Oracle inequality and its consequences

In this section we state the theoretical guarantees for the PAC-Bayes trained network. We will prove an oracle inequality that verifies that the PAC-Bayes estimator is not worse than the optimal choice for \( \vartheta \) and discuss the properties of credible balls. All proofs are postponed to Section 5.

#### 3.1 Oracle inequality

For an active set \( \mathcal{I} \), we define the **oracle choice** on \( \mathcal{S}_T \) from \([2.3]\) as

\[
\vartheta^{*}_T \in \arg \min_{\vartheta \in \mathcal{S}_T} R(\vartheta) \tag{3.1}
\]

which is not accessible to the practitioner because \( R(\vartheta) \) depends on the unknown distribution of \((X, Y)\). A solution to the minimization problem in \((3.1)\) always exists since \( \mathcal{S}_T \) is compact and \( \vartheta \mapsto R(f_\vartheta) \) is

[https://git.scc.kit.edu/vk8868/mcmc-by-backprop]
continuous. If there is more than one solution, we choose one of them. Our main result gives a theoretical guarantee that the PAC-Bayes estimator \( \hat{f}_0 \) from [2.6] is at least as good as the oracle \( \delta^*_2 \) in terms of the excess risk. To this end, we need some mild assumptions on the regression model.

**Assumption 1.**

1. For \( K, C \geq 1 \) we have \( \max_{i=1,\ldots,p} \mathbb{E}_f[X_i^2] \leq K \) and \( \|f\|_\infty \leq C \).

2. \( \varepsilon \) is conditionally on \( X \) sub-Gaussian. More precisely, there are constants \( \sigma, \Gamma > 0 \) such that

\[
\mathbb{E}_f[\varepsilon^k | X] \leq \frac{k!}{2} \sigma^2 \Gamma^{k-2} \text{ a.s., for all } k \geq 2.
\]

Note that neither the loss function nor the data are assumed to be bounded. We obtain the following non-asymptotic oracle inequality:

**Theorem 2** (PAC-Bayes oracle inequality). Under Assumption 1 let \( w = 16C(\Gamma + (2C)) \) and choose

\[
\lambda = \frac{n}{16(C^2 + \sigma^2) + w}.
\]

Then, for sufficiently large \( n \) and for all \( \delta \in (0, 1) \), we have with \( \mathbb{P}_f \otimes \Pi_\lambda(\cdot | D) \)-probability of at least \( 1 - \delta \), that

\[
\mathcal{E}(\hat{f}_\lambda) \leq \min_{\mathcal{I}} \left( 4\mathcal{E}(f_{\delta^*_2}) + \frac{3}{n} (|\mathcal{I}|L \log(p \vee n \vee |\bar{p}|_\infty \vee L) + \log \left( \frac{2}{\delta} \right) \right)
\]

where \( \Xi_1 \) is a constant only depending on the constants from Assumption 1 and on \( B, s \).

The right-hand side of (3.2) can be interpreted similarly to the classical bias-variance decomposition in nonparametric statistics. The first term \( \mathcal{E}(f_{\delta^*_2}) = \mathbb{E}_f[(f_{\delta^*_2}(X) - f(X))^2] \) quantifies the approximation error while second term is an upper bound for the stochastic error. In particular, we recover \( \frac{|\mathcal{I}|L \log(p)}{n} \) as the typical error term for estimating high-dimensional vectors with sparsity \( |\mathcal{I}| \). The factor \( 4 \) in the upper bound can be improved to \( (1 + \eta) \) for any \( \eta > 0 \) at the cost of a larger constant \( \Xi_1 \). 

Theorem 2 is in line with classical PAC-Bayes oracle inequalities, see [Alquier (2021)]. Chérief-Abdellatif [2020] has obtained a similar oracle inequality for a variational approximation of the Gibbs posterior distribution, but without the minimum over the active sets. For penalized empirical risk minimization, Taheri et al. [2021] have obtained another oracle inequality with a different dependence on the depth \( L \).

The \( 1 - \delta \) probability with respect to the coupling \( \mathbb{P}_f \otimes \Pi_\lambda(\cdot | D_n) = \Pi_\lambda(d\theta | D_n) \mathbb{P}_f(dD_n) \) takes into account the randomness of the data and of the estimate. Denoting

\[
r_{n,p}^2 := \min_{\lambda} \left( 4\|f_{\delta^*_2} - f\|_{L^2(pX)}^2 + \frac{3}{n} (|\mathcal{I}|L \log(p \vee n \vee |\bar{p}|_\infty \vee L) \right), \tag{3.3}
\]

we can rewrite (3.2) as

\[
\mathbb{E}_f\left[ \Pi_\lambda(\|f_{\delta^*_2} - f\|_{L^2(pX)}^2 > r_{n,p}^2 + t^2 | D_n) \right] \leq 2e^{-nt^2/\Xi_1}, \quad t > 0,
\]

which is a contraction rate result in terms of a frequentist analysis of the nonparametric Bayes method.

An immediate consequence of the previous theorem is an analogous oracle inequality of the posterior mean \( f_\lambda \) from (2.7).

**Corollary 3** (Posterior mean). Under the conditions of Theorem 2 we have with \( \mathbb{P}_f \)-probability of at least \( 1 - \delta \) that

\[
\mathcal{E}(f_\lambda) \leq \min_{\mathcal{I}} \left( 4\mathcal{E}(f_{\delta^*_2}) + \frac{3}{n} (|\mathcal{I}|L \log(p \vee n \vee |\bar{p}|_\infty \vee L) + \log \left( \frac{2}{\delta} \right) \right)
\]

with a constant \( \Xi_2 \) only depending on the constants from Assumption 1 and on \( B, s \).
The infimum over all \( \mathcal{I} \) in the oracle inequalities shows that the estimator may choose a sparse neural network for approximating \( f \) in a data-driven way. In particular, \( \hat{f}_\lambda \) as well as \( f_\lambda \) adapt to the unknown regularity and a potentially lower dimensional structure of \( f \). Using the approximation properties of neural networks, the oracle inequality yields the optimal rate of convergence (up to a logarithmic factor) over the following class of hierarchical functions:

\[
\mathcal{H}(g, d, t, \beta, C_0) := \left\{ g_n \circ \cdots \circ g_0 : [0,1]^p \to \mathbb{R} : g_i = (g_{i,j})_j \in [a_i, b_i]^{d_i} \to [a_{i+1}, b_{i+1}]^{d_{i+1}}, \right. \\
\left. g_{i,j} \text{ depends on at most } t_i \text{ arguments,} \\
g_{i,j} \in C_{t_i}^{d_i}(a_i, b_i, C_0), \text{ for some } |a_i|, |b_i| \leq C_0 \right\},
\]

where \( d := (p, d_1, \ldots, d_q, 1) \in \mathbb{N}^{q+2}, t := (t_0, \ldots, t_q) \in \mathbb{N}^{q+1}, \beta := (\beta_0, \ldots, \beta_q) \in (0, \infty)^{q+1} \) and where \( C_{t_i}^{d_i}(a_i, b_i, C_0) \) denote classical Hölder balls with Hölder regularity \( \beta_i > 0 \). Theorem 2 reveals the following adaptive version of the upper bound by Schmidt-Hieber (2020):

**Proposition 4** (Rates of convergence). Let \( \log p \leq \frac{\log n}{\log n} \) and \( X \in [0,1]^p \). In the situation of Theorem 3 there exists a network architecture \( (L, \vec{p}) = (C_1[\log_2 n], p, C_2 n, \ldots, C_2 n, 1) \) with \( C_1 \) and \( C_2 \) only depending on upper bounds for \( q, (d_1, \ldots, d_q)_\infty, (t_\infty, \beta)_\infty, \) and \( C_0 \) such that the estimators \( \hat{f}_\lambda \) and \( f_\lambda \) yield an excess risk for sufficiently large \( n \) uniformly over all hierarchical functions \( f \in \mathcal{H}(g, d, t, \beta, C_0) \) of at most

\[
\mathcal{E}(\hat{f}_\lambda) \leq \Xi_3 \left( \frac{n}{\log(p n) \log^2(n)} \right)^{2\beta^*/(2\beta^* + t^*)} + \Xi_3 \frac{\log (\frac{\hat{f}_\lambda}{f_\lambda})}{n} \quad \text{and} \quad \mathcal{E}(\hat{f}_\lambda) \leq \Xi_4 \left( \frac{n}{\log(p n) \log^2(n)} \right)^{2\beta^*/(2\beta^* + t^*)} + \Xi_4 \frac{\log (\frac{\hat{f}_\lambda}{f_\lambda})}{n},
\]

with \( \mathbb{P}_f \otimes \Pi_{\lambda} (\cdot \mid \mathcal{D}_n) \)- and \( \mathbb{P}_f \)-probability of at least \( 1 - \delta \), respectively, where \( \beta^* \) and \( t^* \) are given by

\[
\beta^*_i := \beta_i \prod_{i=1}^q (\beta_i \land 1) \quad \text{and} \quad \frac{2\beta^*}{2\beta^* + t^*} = \min_{i=0, \ldots, q} \frac{2\beta^*_i}{2\beta^*_i + t_i}.
\]

The constants \( \Xi_3 \) and \( \Xi_4 \) only depend on \( q, (d_1, \ldots, d_q), t, \beta \) and \( C_0 \) as well as the constants from Assumption 4 and \( B, s \).

For a fixed dimension \( p \) it has been proved by Schmidt-Hieber (2020) that this rate is indeed optimal in a minimax sense up to a logarithmic factor in \( n \). Studying classical Hölder balls \( C_{2i}^{d_i}(0,1]^p, C_0) \), a contraction rate of order \( n^{-2\beta^*/(2\beta^* + p)} \) have been derived by Polson & Rocha (2018) and Chérief-Abdellatif (2020), while Polson & Rocha (2018) have used a hierarchical prior to obtain adaptivity with respect to \( \beta \) and the result by Chérief-Abdellatif (2020) is non-adaptive, but incorporates a variational Bayes method.

### 3.2 Credible sets

In addition to the adaptivity, the Bayesian approach offers a possibility for uncertainty quantification. We define the credible ball

\[
\hat{C}(\tau_\alpha) := \{ h \in L^2 : \| h - \hat{f}_\lambda \|_{L^2(\mathbb{P}^X)} \leq \tau_\alpha \}, \quad \alpha \in (0,1),
\]

with critical values

\[
\tau_\alpha := \arg \inf_{\tau > 0} \left\{ \Pi_{\lambda}(\theta : \| f_{\theta} - \hat{f}_\lambda \|_{L^2(\mathbb{P}^X)} \leq \tau \mid \mathcal{D}_n) > 1 - \alpha \right\}.
\]

By construction \( \hat{C}(\tau_\alpha) \) is the smallest \( L^2 \)-ball around \( \hat{f}_\lambda \) which contains \( 1 - \alpha \) mass of the Gibbs posterior measure. Despite the posterior belief, it is not necessarily guaranteed that the true regression function
is contained in \( \hat{C}(\tau_n) \). More precisely, the posterior distribution might be quite certain, in the sense that the credible ball is very narrow, but it suffers from a significant bias. In general, it might happen that \( \mathbb{P}_f(f \in \hat{C}(\tau_n)) \to 0 \), see e.g. [Knapik et al. (2011) Theorem 4.2] in a Gaussian model. To compensate for this lack of coverage, [Rousseau & Szabó (2020)] have introduced inflated credible balls where the critical value is multiplied with a slowly diverging factor. While they proved that this method works in several classical nonparametric models with a sieve prior, our neural network setting causes an additional problem. In order to prove coverage, we have to compare norms in the intrinsic parameter space, i.e. the space of the network weights, with the norm of the resulting predicted regression function. While \( \|f_\theta\|_{L^2(\mathbb{R}^d \times \mathcal{X})} \) can be upper bounded with the maximum norm of \( \vartheta \), see [Lemma 9] below, the converse direction does not hold. Even locally around an oracle choice \( \vartheta_0 \) it is not clear whether such a bound holds true. As a consequence, we define another critical value at the level of the parameter space

\[
\tau_\alpha^T := \arg \inf_{\tau > 0} \{ \Pi_{\lambda,\lambda}(\vartheta : |\vartheta - \hat{\vartheta}_{\lambda}|_\infty \leq \tau \mid \mathcal{D}_n) > 1 - \alpha \}, \quad \hat{\vartheta}_{\lambda} := \int \vartheta \Pi_{\lambda,\lambda}(d\vartheta \mid \mathcal{D}_n),
\]

where we have fixed an active set \( \mathcal{I} \) and \( \Pi_{\lambda,\lambda}(\cdot \mid \mathcal{D}_n) \propto \exp(-\lambda R_n(\vartheta)) \Pi_\mathcal{I}(d\vartheta) \) denotes the posterior distribution with respect to \( \Pi_\mathcal{I} \). Both critical values measure the fluctuation of the posterior around its mean and we compare both empirically in our simulations. The theoretical properties of the credible ball are summarized in the following theorem:

**Theorem 5** (Credible balls). Under the conditions of Theorem 2 and with \( r_{n,p}^2 \) from (3.3) we have for all \( \alpha \in (0,1) \) that

\[
\mathbb{P}_f\left( \text{diam}(\hat{C}(\tau_n)) \leq 4 \sqrt{r_{n,p}^2 + 2(\Xi_1 + \Xi_2) \frac{n \log 2}{\alpha}} \right) \geq 1 - \alpha.
\]

If \( \mathcal{I} \) is an active set such that \( \mathcal{E}(f_{\vartheta_0}^2) \) and \( \lambda^{-1} |\mathcal{I}| \) are of the order \( r_{n,p}^2 \), then we have for some constant \( \xi > 0 \) depending on \( \bar{p}, L \), the constants from [Assumption 7] \( B, s \) and \( \alpha \) that

\[
\mathbb{P}_f(f \in \hat{C}(\xi \tau_\alpha^T)) \geq 1 - \alpha.
\]

Therefore, the order of the diameter of \( \hat{C}(\tau_n) \) is of the best possible size. On the other hand, the larger credible set \( \hat{C}(\xi \tau_\alpha^T) \) defines an honest confidence set for a fixed class \( \mathcal{H}(q, d, t, \beta, C_n) \) of regression functions if \( \xi \) is chosen sufficiently large depending on the class parameters. In that sense \( \xi \) is a non-asymptotic version of the inflation factor by [Rousseau & Szabó (2020)]. To circumvent the unknown constant \( \xi \), we can conclude from Theorem 5 that

\[
\mathbb{P}_f(f \in \hat{C}((\log n)r_{n,p}^2)) \geq 1 - \alpha \quad \text{for sufficiently large } n.
\]

It has to be noted that \( \hat{C}(\xi \tau_\alpha^T) \) is not an adaptive confidence set, because we have to choose the correct active set \( \mathcal{I} \) for \( \tau_\alpha^T \). It is well known that adaptive honest confidence sets are only possible under additional assumptions, e.g. self-similarity or polished tail conditions, on the regression function, see [Hoffmann & Nickl (2011)] and we remark that such conditions with respect to the network parametrization seem infeasible.

### 4 Numerical examples

In this section, we test the MCMC by backprop algorithm on simulated data. For dimensions \( p \in \{1, 10, 100\} \) the explanatory variables \( \mathbf{X} \) follow a uniform distribution on \([0, 1]^p\). For \( p = 1 \), the regression function is chosen as

\[
f(x) = \sin(2\pi x^2),
\]

whereas for \( p \in \{10, 100\} \) it is

\[
f(x) = \sin(2\pi|x|^2)
\]
with a fixed, but randomly generated sparse matrix \( A \in \mathbb{R}^{2 \times p} \) with \( \ell^2 \)-standardized rows and two non-zero entries per row. The resulting output variables are generated by \( Y = f(X) + \varepsilon \) with normally distributed observation errors \( \varepsilon \sim \mathcal{N}(0, 0.01) \). We draw a sample of size \( n = 1,000 \) which is randomly split into a training set of size \( n_{\text{train}} = 750 \) and a testing set of size \( n_{\text{test}} = 250 \).

We compare the estimation accuracy of our estimation methods against that of the neural network estimator \( \hat{f}_{\text{GD}} \) which is trained with the standard gradient descent optimization of the empirical risk. For both methods the network architecture is \( (L, \bar{p}) = (3, (p, 8, 8, 8, 1)) \). In accordance with common implementations of neural network training algorithms, we additionally include a shift \( \bar{b}^{(L+1)} \in \mathbb{R} \) in the output layer. Thus, the resulting parameter dimensions are \( \bar{p} \in \{169, 241, 961\} \). For the MCMC by backprop algorithm, the temperature parameter is set to \( \lambda = 5n_{\text{train}} \) and the learning rate is \( \gamma = 0.01 \). We choose a burn in time of \( b = 50,000 \) and draw \( m = 100 \) times with gap length \( c = 100 \). The gradient descent algorithm uses 50,000 steps with the same learning rate \( \gamma = 0.01 \). Running the MCMC by backprop algorithm with the full prior \( \Pi^* \), we obtain \((\hat{\theta}^{(b+c)})_{k=1,\ldots,m}\) and denote by \( \hat{f}_{\theta_k} := f(\hat{\theta}^{(b+c)}) \).

We observe a considerable improvement of PAC-Bayes trained networks compared to the naive gradient descent and the posterior mean with the full prior. On average, about 46% of the weights are nonzero for \( \alpha = 0.05 \). While Figures 1 and 2 only show one realization for the training process of the estimates, Table 1 summarizes the performance of all methods in a Monte Carlo simulation with 50 Monte Carlo iterations. We observe a considerable improvement of PAC-Bayes trained networks compared to the naive gradient descent method even with just a single drawing from the posterior with the full prior. Using the posterior mean \( f_{\lambda} \) improves the performance even further. In a typical run, our methods yield a smaller excess risk. In general, our methods are far more robust, whereas the gradient descent algorithm is prone to getting stuck in a suboptimal local minimum as indicated by the large mean and standard deviation of its excess risk.

Running the algorithm again, now with the mixing prior \( \Pi \) and sparsity parameter \( s = 2 \), we analogously obtain \( f_{\lambda} \). Here, about half of the weights and shifts were randomly set to 0 in the initialization. In the high-dimensional setting \( p = 100 \), our algorithm benefits from incorporating sparsity and outperforms both the gradient descent and the posterior mean with the full prior. On average, about 42% of the weights are nonzero for \( p = 100 \), as compared to 47% and 46% for \( p = 1 \) and \( p = 10 \), respectively.

To study the empirical coverage properties of the credible sets for \( \alpha = 0.05 \), we use the drawings \((\hat{\theta}^{(b+c)})_{k=1,\ldots,m}\) to approximate \( \tau^*_{\alpha} := \tau_{\alpha}^* \). By the law of large numbers, \( z_k \) serves as a proxy for \( \|f(\hat{\theta}^{(b+c)}) - f_{\lambda}^*\|_{L^2(\mathbb{P}_X)} = \mathbb{E}[\|f(\hat{\theta}^{(b+c)}) - f_{\lambda}^*\|^2(X)] \). Denote by \( q_{1-\alpha} \) the empirical 1 - \( \alpha \) quantile of \( z = (z_1, \ldots, z_m) \) and check whether

\[
\frac{1}{M} \sum_{j=1}^{M} (f - f_{\lambda}^*)^2(\tilde{X}_j) \leq q_{1-\alpha}.
\]

Averaging over the 50 MC iterations, we obtain approximations for both \( \tau_{\alpha} \) and \( P_f( f \in \hat{C}(\tau_{\alpha}) ) \). Similarly,
one obtains approximations for $\tau^\bullet_\alpha$ and $P_f(f \in \hat{C}(\tau^\bullet_\alpha))$. The results are summarized in Table 2. For $p = 1$, we get good coverage even for the ball with radius $\tau_\alpha$, while $\hat{C}(\log(n_{\text{train}})\tau^\bullet_\alpha)$ actually achieves full coverage. For $p \in \{10, 100\}$, the radius of $\hat{C}(\tau_\alpha)$ (as well as the radius of $\hat{C}(\tau^\bullet_\alpha)$) is too small to contain the true regression function. This is in line with our theoretical result, that the inflation factor for the radius is needed to verify coverage of $f$ by the credible ball $\hat{C}(\log(n_{\text{train}})\tau^\bullet_\alpha)$. Indeed, $\hat{C}(\log(n_{\text{train}})\tau^\bullet_\alpha)$ achieves good coverage in all three scenarios.

5 Proofs

5.1 A PAC-Bayes bound

Let $\mu, \nu$ be probability measures on a measurable space $(E, \mathcal{A})$. The Kullback-Leibler divergence of $\mu$ with respect to $\nu$ is defined via

$$KL(\mu, \nu) := \begin{cases} \int \log \left( \frac{d\mu}{d\nu} \right) d\mu, & \text{if } \mu \ll \nu \\ \infty, & \text{otherwise} \end{cases}.$$  

The following classical lemma is a key ingredient for PAC-Bayes bounds. A proof can be found in [Catoni (2004), p. 159] or [Alquier (2021)].

Lemma 6. Let $h : E \to \mathbb{R}$ be a measurable function such that $\int \exp \circ h \, d\mu < \infty$. With the convention $\infty - \infty = -\infty$, it then holds that

$$\log \left( \int \exp \circ h \, d\mu \right) = \sup_{\nu} \left( \int h d\nu - KL(\nu, \mu) \right),$$  

(5.1)
where the supremum and the infimum are taken over all probability measures \( \nu \) on \((E, \mathcal{A})\). If additionally, \( h \) is bounded from above on the support of \( \mu \), then the supremum in (5.1) is attained for \( \nu = g \) with the Gibbs distribution \( g \), i.e. \( \frac{dg}{d\mu} \propto \exp \circ h \).

Note that no generality is lost by considering only those probability measures \( \nu \) on \((E, \mathcal{A})\) such that \( \nu \ll \mu \) and thus

\[
\log \left( \int \exp \circ h \, d\mu \right) = - \inf_{\nu \ll \mu} (\text{KL}(\nu, \mu) - \int h \, d\nu).
\]

Next we state a Bernstein type inequality for the excess risk \( \mathcal{E}(\vartheta) := \mathcal{E}(f_{\vartheta}) = R(\vartheta) - E[f(\mathbf{Y} - f(\mathbf{X}))^2] \). Its proof is given in Section 5.5.

**Lemma 7.** Set \( \mathcal{E}(\vartheta) := R(\vartheta) - R(f) \) and \( \mathcal{E}_n(\vartheta) := R_n(\vartheta) - R_n(f) \). For \( C_{n,\lambda} := \frac{8(C^2 + \sigma^2)}{\Gamma(w/n)} \cdot \frac{\lambda}{n} \) and \( w = 16C(\Gamma \vee 2C) \), we have for all \( \lambda \in [0, n/w) \) that

\[
\max \left\{ E_f \left[ \exp \left( \lambda (\mathcal{E}(\vartheta) - \mathcal{E}_n(\vartheta)) \right) \right], E_f \left[ \exp \left( \lambda (\mathcal{E}_n(\vartheta) - \mathcal{E}(\vartheta)) \right) \right] \right\} \leq \exp \left( C_{n,\lambda} \lambda \mathcal{E}(\vartheta) \right).
\]

Based on these two Lemmas, we can verify a PAC-Bayes bound for the excess risk. The basic proof strategy is standard in the PAC-Bayes literature, see e.g. Alquier & Biau (2013).

**Proposition 8 (PAC-Bayes bound).** For any \( \mathcal{D}_n \)-dependent (in a measurable way) probability measure \( \rho \ll \Pi \) and any \( \lambda \in (0, n/w) \) such that \( C_{n,\lambda} \leq 1/2 \), we have

\[
\mathcal{E}(\hat{\vartheta}_\lambda) \leq 3 \int \mathcal{E} d\rho + \frac{4}{\lambda} \left( \text{KL}(\rho, \Pi) + \log \left( \frac{2}{\delta} \right) \right)
\]

with \( P_f \otimes \Pi(\cdot | \mathcal{D}_n) \)-probability of at least \( 1 - \delta \).
For the posterior distribution \( \vartheta \) concludes Lemma 7 yields

\[
\text{Proof.} \quad \text{Lemma 7 yields}
\]

\[
1 \text{ Since provided with respect to the prior probability measure } \alpha \text{ iterations.}
\]

\[
\text{Table 1: Average (and standard deviation) of the excess risk in a Monte Carlo simulation with 50 MC iterations.}
\]

\[
\begin{array}{lcl}
p = 1 & p = 10 & p = 100 \\
\hline
\hat{f}^* & 0.0012 (0.0007) & 0.1504 (0.0638) & 0.3094 (0.0532) \\
\hat{f}^*_\alpha & 0.0026 (0.0010) & 0.1566 (0.0638) & 0.3161 (0.0510) \\
f_\alpha & 0.0069 (0.0115) & 0.2335 (0.1108) & 0.2621 (0.0648) \\
\hat{f}_{GD} & 0.0573 (0.1056) & 0.2471 (0.1367) & 0.4105 (0.0889)
\end{array}
\]

\[
\text{Table 2: Coverage probabilities (and average radii) of credible sets for } \alpha = 0.05 \text{ in a Monte Carlo simulation with 50 MC iterations.}
\]

\[
\begin{array}{lcl}
p = 1 & p = 10 & p = 100 \\
\hline\hat{C}(\tau_n) & 84\% (0.0463) & 0\% (0.3818) & 0\% (0.5498) \\
\hat{C}(\log(\mu_{\text{train}}\tau_n^*) & 100\% (1.8207) & 88\% (0.7555) & 100\% (1.8402)
\end{array}
\]

\[
\text{Proof.} \quad \text{Lemma 7 yields}
\]

\[
\max \left\{ \mathbb{E}_f \left[ \exp \left( \lambda (1 - C_{n,\lambda}) \mathcal{E}(\vartheta) - \lambda \mathcal{E}_n(\vartheta) - \log \delta^{-1} \right) \right], \mathbb{E}_f \left[ \exp \left( \lambda \mathcal{E}_n(\vartheta) - \lambda (1 + C_{n,\lambda}) \mathcal{E}(\vartheta) - \log \delta^{-1} \right) \right] \right\} \leq \delta.
\]

Integrating in \( \vartheta \) with respect to the prior probability measure \( \Pi \) and applying Fubini’s theorem, we conclude

\[
\mathbb{E}_f \left[ \int \exp \left( \lambda (1 - C_{n,\lambda}) \mathcal{E}(\vartheta) - \lambda \mathcal{E}_n(\vartheta) - \log \delta^{-1} \right) d\Pi(\vartheta) \right] \leq \delta \quad \text{and}
\]

\[
\mathbb{E}_f \left[ \int \exp \left( \lambda \mathcal{E}_n(\vartheta) - \lambda (1 + C_{n,\lambda}) \mathcal{E}(\vartheta) - \log \delta^{-1} \right) d\Pi(\vartheta) \right] \leq \delta. \quad (5.3)
\]

For the posterior distribution \( \Pi_{1,\lambda}(\cdot|D_n) \ll \Pi \) with corresponding Radon-Nikodym density

\[
\frac{d\Pi_{1,\lambda}(\vartheta|D_n)}{d\Pi(\vartheta)} = D_\lambda^{-1} \exp(-\lambda R_n(\vartheta)), \quad D_\lambda := \int \exp(-\lambda R_n(\vartheta)) d\Pi(\vartheta)
\]

with respect to \( \Pi \), we obtain

\[
\mathbb{E}_{D_n, \tilde{\vartheta} \sim \Pi_{1,\lambda}(\cdot|D_n)} \left[ \exp \left( \lambda (1 - C_{n,\lambda}) \mathcal{E}(\tilde{\vartheta}) - \lambda \mathcal{E}_n(\tilde{\vartheta}) - \log \delta^{-1} + \lambda R_n(\tilde{\vartheta}) + \log D_\lambda \right) \right] \\
= \mathbb{E}_{D_n, \tilde{\vartheta} \sim \Pi_{1,\lambda}(\cdot|D_n)} \left[ \exp \left( \lambda (1 - C_{n,\lambda}) \mathcal{E}(\tilde{\vartheta}) - \lambda \mathcal{E}_n(\tilde{\vartheta}) - \log \delta^{-1} - \log \left( \frac{d\Pi_{1,\lambda}(\vartheta|D_n)}{d\Pi(\vartheta)} \right) \right) \right] \\
= \mathbb{E}_{D_n} \left[ \int \exp \left( \lambda (1 - C_{n,\lambda}) \mathcal{E}(\vartheta) - \lambda \mathcal{E}_n(\vartheta) - \log \delta^{-1} \right) d\Pi(\vartheta) \right] \leq \delta.
\]

Since \( \mathbb{1}_{[0,\infty]}(x) \leq e^{\lambda x} \) for all \( x \in \mathbb{R} \), we deduce with probability not larger than \( \delta \) that

\[
(1 - C_{n,\lambda}) \mathcal{E}(\vartheta) - \mathcal{E}_n(\vartheta) + R_n(\vartheta) - \lambda^{-1} \left( \log \delta^{-1} - \log D_\lambda \right) \geq 0.
\]

Provided \( (1 - C_{n,\lambda}) > 0 \), we thus have with \( \mathbb{P} \otimes \Pi_{1,\lambda}(\cdot|D_n) \)-probability of at least \( 1 - \delta \):

\[
\mathcal{E}(\vartheta) \leq \frac{1}{1 - C_{n,\lambda}} \left( - R_n(f) + \lambda^{-1} \left( \log \delta^{-1} - \log D_\lambda \right) \right).
\]
Therefore, we conclude with probability of at least $1 - \delta$:
\[
\mathcal{E}(\hat{\theta}) \leq \frac{1}{1 - C_{n,\lambda}} \inf_{\rho \ll \Pi} \left( \int \mathcal{E}_n(\vartheta) d\rho(\vartheta) + \lambda^{-1} \left( \log \delta^{-1} + KL(\rho, \Pi) \right) \right).
\]

In order to reduce the integral $\int \mathcal{E}_n(\vartheta) d\rho(\vartheta)$ to $\int \mathcal{E}(\vartheta) d\rho(\vartheta)$, we use Jensen's inequality and (5.3) to obtain for any probability measure $\rho \ll \Pi$ (which may depend on $\mathcal{D}_n$)
\[
\mathbb{E}_{\mathcal{D}_n} \left[ \exp \left( \int \lambda \mathcal{E}_n(\vartheta) - \lambda (1 + C_{n,\lambda}) \mathcal{E}(\vartheta) d\rho(\vartheta) - KL(\rho, \Pi) - \log \delta^{-1} \right) \right] \leq \mathbb{E}_{\mathcal{D}_n, \vartheta \sim \rho} \left[ \exp \left( \lambda \mathcal{E}_n(\vartheta) - \lambda (1 + C_{n,\lambda}) \mathcal{E}(\vartheta) - \log \delta^{-1} \right) \right] \leq \mathbb{E}_{\mathcal{D}_n} \left[ \int \exp \left( \lambda \mathcal{E}_n(\vartheta) - \lambda (1 + C_{n,\lambda}) \mathcal{E}(\vartheta) - \log \delta^{-1} \right) d\Pi(\vartheta) \right] \leq \delta.
\]

Using $I_{[\rho, \infty)}(x) \leq e^x$ again, we conclude with probability of at least $1 - \delta$:
\[
\int \mathcal{E}_n(\vartheta) d\rho(\vartheta) \leq (1 + C_{n,\lambda}) \int \mathcal{E}(\vartheta) d\rho(\vartheta) + \lambda^{-1} \left( KL(\rho, \Pi) + \log \delta^{-1} \right).
\]

Therefore, we conclude with probability of at least $1 - 2\delta$
\[
\mathcal{E}(\hat{\theta}) \leq \frac{1}{1 - C_{n,\lambda}} \inf_{\rho \ll \Pi} \left( (1 + C_{n,\lambda}) \int \mathcal{E}(\vartheta) d\rho(\vartheta) + \frac{2}{\lambda} \left( \log \delta^{-1} + KL(\rho, \Pi) \right) \right)
\]

which yields the claimed bound if $C_{n,\lambda} \leq 1/2$.

\section*{5.2 Proof of Theorem 2}

We fix some index set $I$, a radius $\eta \in (0, 1]$ and apply Proposition 8 with $\rho = \rho_{\pi, \eta}$ defined via
\[
\frac{d\rho_{\pi, \eta}}{d\Pi}(\vartheta) \propto I_{\{||\vartheta - \vartheta^*||_2 \leq \eta\}}
\]

with $\vartheta^*$ from (3.1). Note that indeed $C_{n,\lambda} \leq 1/2$ for the given choice of $\lambda$. In order to control the integral term, we decompose
\[
\int \mathcal{E} d\rho = \mathcal{E}(\vartheta^*_2) + \int \mathbb{E}_f \left[ (f_\vartheta(X) - f(X))^2 - (f_\vartheta^*_2(X) - f(X))^2 \right] d\rho(\vartheta)
\]

\[
\leq \mathcal{E}(\vartheta^*_2) + \int \mathbb{E}_f \left[ (f_\vartheta(X) - f(X))^2 \right] d\rho(\vartheta)
\]

\[
\leq \frac{4}{3} \mathcal{E}(\vartheta^*_2) + 4 \int \mathbb{E}_f \left[ (f_\vartheta(X) - f(X))^2 \right] d\rho(\vartheta),
\]

using $2ab \leq \frac{a^2}{T} + 3b^2$ in the last step. To bound the remainder, we use the Lipschitz continuity of the map $\vartheta \mapsto f_\vartheta(X)$ for fixed $x$. 

\begin{equation}
\end{equation}
Lemma 9. Let $\theta, \tilde{\theta} \in [-B, B][\rho]$. Then we have for $x \in \mathbb{R}^p$ that

$$|f_\theta(x) - f_{\tilde{\theta}}(x)| \leq 2(|x|_1 \vee 1)(L + 2)(2|\rho|_{\infty}B)^L \cdot |\theta - \tilde{\theta}|_\infty.$$ 

Due to the support of $\rho = \rho_{\mathcal{I}, \eta}$, we obtain

$$\int \mathcal{E} d\rho \leq \frac{4}{3} \mathcal{E}(\theta^*_\mathcal{I}) + \frac{4}{n^2}$$ for $n = \frac{1}{4(L + 2)(2|\rho|_{\infty}B)^L p^2 Kn}$. (5.6)

It remains to bound the Kullback-Leibler term in (5.2) which can be done with the following lemma:

**Lemma 10.** We have

(i) $\text{KL}(\rho_{\mathcal{I}, \eta}, \Pi) = \text{KL}(\rho_{\mathcal{I}, \eta}, \Pi_{\mathcal{I}}) + \log(C_{\mathcal{I}})$ where $C_{\mathcal{I}} := C_s |\mathcal{I}| \left(\frac{|\rho|}{|\mathcal{I}|}\right)$.

(ii) $\text{KL}(\rho_{\mathcal{I}, \eta}, \Pi) \leq |\mathcal{I}| \log(\eta^{-1}2B)$.

In particular,

$$\text{KL}(\rho_{\mathcal{I}, \eta}, \Pi) \leq |\mathcal{I}| \log(\eta^{-1}2B) + \log(C_{\mathcal{I}}).$$

Together with (5.6) and (5.7) by Stirling’s formula, the previous lemma yields

$$\text{KL}(\rho, \Pi) \leq |\mathcal{I}| \log(\eta^{-1}2C_sB|\rho|_{\infty}).$$ (5.7)

Plugging (5.6) and (5.7) into the PAC-Bayes bound (5.2) we conclude

$$\mathcal{E}(\tilde{\theta}_\lambda) \leq 4\mathcal{E}(\theta^*_\mathcal{I}) + \frac{4}{n^2} + \frac{4}{n}(|\mathcal{I}| \log (8(L + 2)(2|\rho|_{\infty}B)^L p^2 KS|\rho|_{\infty}e) + \log \left(\frac{2}{\lambda}\right)),$$

$$\leq 4\mathcal{E}(\theta^*_\mathcal{I}) + \frac{4}{n}(|\mathcal{I}| \log (p \vee n \vee |\rho|_{\infty} \vee L \vee B \vee K \vee s) + \log \left(\frac{2}{\lambda}\right))$$ (5.8)

for some constant $\Xi$ independent of $p, n, \rho$ and $L$. Note that the upper bound in (5.8) is deterministic and $\mathcal{I}$ is arbitrary. Therefore, we can choose $\mathcal{I}$ such that this bound is minimized, which completes the proof. 

5.3 **Proof of Theorem 5**

Since Theorem 2 and Corollary 3 yield max $\{\mathbb{E}_f[\lambda] : \|f_\theta - f\|_{L^2(\mathcal{D})} \leq s_{n,p}, \mathcal{D}_n\} \geq 1 - \frac{\alpha}{2}$ with $s_{n,p} := r_{n,p}^2 + \frac{(\mathbb{E}_f(\lambda) + \frac{15}{2})}{n} \log \frac{2}{\alpha}$, we conclude

$$\mathbb{P}_f(\text{diam}(\tilde{C}_{\tau_n}) \leq 4s_{n,p}) = \mathbb{P}_f(\sup_{g,h \in C(\tau_n)} \|g - h\|_{L^2(\mathcal{D})} \leq 4s_{n,p})$$

$$\geq \mathbb{P}_f(\sup_{g,h \in C(\tau_n)} \|g - f\|_{L^2(\mathcal{D})} + \|f - h\|_{L^2(\mathcal{D})} \leq 4s_{n,p})$$

$$\geq \mathbb{P}_f(\tau_n \leq 2s_{n,p})$$

$$= \mathbb{P}_f(\Pi_{\mathcal{I}}(\theta : \|f_\theta - f\|_{L^2(\mathcal{D})} \leq 2s_{n,p}, \mathcal{D}_n) > 1 - \alpha)$$

$$= \mathbb{P}_f(\Pi_{\mathcal{I}}(\theta : \|f_\theta - f\|_{L^2(\mathcal{D})} > 2s_{n,p}, \mathcal{D}_n) \geq \alpha)$$

$$= 1 - \mathbb{P}_f(\Pi_{\mathcal{I}}(\theta : \|f_\theta - f\|_{L^2(\mathcal{D})} > 2s_{n,p}, \mathcal{D}_n) \geq \alpha)$$

$$\geq 1 - \frac{1}{\alpha} \mathbb{E}_f[\Pi_{\mathcal{I}}(\theta : \|f_\theta - f\|_{L^2(\mathcal{D})} > 2s_{n,p}, \mathcal{D}_n)]$$

$$\geq 1 - \frac{1}{\alpha} \mathbb{E}_f[\Pi_{\mathcal{I}}(\theta : \|f_\theta - f\|_{L^2(\mathcal{D})} > s_{n,p}, \mathcal{D}_n)]$$

15
\[ + \mathbb{P}_f(\|f_\lambda - f\|_{L^2(\mathbb{X})} > s_{n,p}) \]
\[ \geq 1 - \alpha. \]

The first statement in [Theorem 5] is thus verified.

For the coverage statement, we first bound
\[ \mathbb{P}_f( f \in \tilde{C}(\xi^T \tau)) = \mathbb{P}_f(\|f - \tilde{f}_\lambda\|_{L^2(\mathbb{X})} \leq \xi^T \tau) \]
\[ \geq \mathbb{P}_f(\Pi_{\lambda}(\theta : |\theta - \tilde{\theta}_\lambda|_\infty \leq \xi^{-1} \|f - \tilde{f}_\lambda\|_{L^2(\mathbb{X})} | \mathcal{D}_n) \leq 1 - \alpha) \]
\[ \geq \mathbb{P}_f(\Pi_{\lambda}(\theta : |\theta - \tilde{\theta}_\lambda|_\infty \leq \xi^{-1}s_{n,p} | \mathcal{D}_n) \leq 1 - \alpha - \alpha^2 \]
\[ = 1 - \alpha^2 - \mathbb{P}_f(\Pi_{\lambda}(\theta : |\theta - \tilde{\theta}_\lambda|_\infty \leq \xi^{-1}s_{n,p} | \mathcal{D}_n) > 1 - \alpha) \]
\[ \geq 1 - \alpha^2 - \frac{1}{1 - \alpha} \mathbb{E}_f[\Pi_{\lambda}(B_{n,p} | \mathcal{D}_n)] \]

with
\[ B_{n,p} := \{ \theta : |\theta - \tilde{\theta}_\lambda|_\infty \leq \xi^{-1}s_{n,p} \}. \]

Recall that we now use the prior \( \Pi_{\lambda} \) without mixing and a network class with an optimal network architecture, i.e. \( N = |\mathcal{I}| \) is of the order \( \lambda s_{n,p}^2 \) and \( \mathcal{E}(\theta^*_\mathcal{I}) = \mathcal{O}(s_{n,p}^2) \). We have with \( D_{\lambda}: = \int \exp(-\lambda R_n(\theta)) \, d\Pi_{\lambda}(\theta) \) that
\[ \mathbb{E}_f[\Pi_{\lambda}(B_{n,p}|\mathcal{D}_n)] = \mathbb{E}_f[D_{\lambda}^{-1} \int_{B_{n,p}} e^{-\lambda R_n(\theta)} \Pi_{\lambda}(d\theta)] \]
\[ = \mathbb{E}_f[D_{\lambda}^{-1} \int_{B_{n,p}} e^{-\lambda \mathcal{E}_n(\theta)} \Pi_{\lambda}(d\theta)e^{-\lambda R_n(f)}] \]
\[ \leq \mathbb{E}_f[D_{\lambda}^{-1} \Pi_{\lambda}(B_{n,p})e^{-\lambda R_n(f)}] \]
\[ \leq \exp(|\mathcal{I}| \log \frac{s_{n,p}}{2B}) \mathbb{E}_f[D_{\lambda}^{-1} e^{-\lambda R_n(f)}], \]

where we used \( \Pi_{\lambda}(B_{n,p}) \leq \exp \left( |\mathcal{I}| \log \frac{s_{n,p}}{2B} \right) \) due to the uniform distribution of the prior. Based on [5.4] we obtain
\[ \mathbb{E}_f[\Pi_{\lambda}(B_{n,p}|\mathcal{D}_n)] \leq \exp \left( |\mathcal{I}| \log \frac{s_{n,p}}{2B} \right) \mathbb{E}_f \left[ \exp \left( \inf_{\rho \in \Pi_{\lambda}} \left( KL(\rho, \Pi_{\lambda}) + \int \lambda \mathcal{E}_n(\theta) \, d\rho(\theta) \right) - \lambda R_n(f) \right) \right] \]
\[ = \exp \left( |\mathcal{I}| \log \frac{s_{n,p}}{2B} \right) \mathbb{E}_f \left[ \exp \left( \inf_{\rho \in \Pi_{\lambda}} \left( KL(\rho, \Pi_{\lambda}) + \int \lambda \mathcal{E}_n(\theta) \, d\rho(\theta) \right) \right) \right]. \]

For \( \rho = \rho_{\mathcal{I}, \eta'} \) defined via
\[ \frac{d\rho_{\mathcal{I}, \eta'}(\theta)}{d\Pi_{\lambda}}(\theta) \propto 1_{\{|\theta - \tilde{\theta}_\lambda|_\infty \leq \eta' \}}, \quad \eta' = \frac{s_{n,p}}{4(L + 2(2|\tilde{\theta}_\lambda|_\infty B)^2 p R)} \]
we can moreover estimate with [5.5] [Lemma 9 and Lemma 10]
In the sequel $\Xi_i > 0, i = 5, 6, \ldots$, are numerical constants which may depend on $\vec{p}, B, K, L, p$. Since $\mathcal{E}(\vartheta^2_2) = O(s_{n,p}^2)$ and $|\mathcal{I}| = O(\lambda s_{n,p}^2)$, we obtain

$$E_f\left[\Pi_{\mathcal{I}, \lambda}(B_{n,p} | \mathcal{D}_n)\right] \leq E_f\left[\exp \left(-|\mathcal{I}| \log \xi + \Xi_6 \lambda s_{n,p}^2 + \Xi_7 \lambda s_{n,p}^2 + \lambda \int (\mathcal{E}_n(\vartheta) - \mathcal{E}(\vartheta)) \, d\rho_{\mathcal{I}, \eta}(\vartheta)\right)\right]$$

$$\leq \exp \left(-|\mathcal{I}| \log \xi + \Xi_6 \lambda s_{n,p}^2 + \Xi_7 \lambda s_{n,p}^2\right)$$

applying Jensen’s inequality in the last line. To bound the expectation in the previous line, Fubini’s theorem, Lemma 7 and Lemma 9 imply

$$E_f\left[\int \exp \left(\lambda (\mathcal{E}_n(\vartheta) - \mathcal{E}(\vartheta))\right) \, d\rho_{\mathcal{I}, \eta}(\vartheta)\right]$$

$$= \int E_f\left[\exp \left(\lambda (\mathcal{E}_n(\vartheta) - \mathcal{E}(\vartheta))\right)\right] \, d\rho_{\mathcal{I}, \eta}(\vartheta)$$

$$\leq \int \exp \left(\lambda C_n, \lambda \mathcal{E}(\vartheta)\right) \, d\rho_{\mathcal{I}, \eta}(\vartheta)$$

$$\leq \int \exp \left(2\lambda C_n, \lambda \left(\mathcal{E}(\vartheta^2_2) + \|f_\theta - f_{\vartheta^2_2}\|_{L^2(p, X)}^2\right)\right) \, d\rho_{\mathcal{I}, \eta}(\vartheta)$$

$$\leq \int \exp \left(2\lambda C_n, \lambda \left(\mathcal{E}(\vartheta^2_2) + s_{n,p}^2\right)\right) \, d\rho_{\mathcal{I}, \eta}(\vartheta)$$

$$\leq e^{\Xi_\lambda \lambda s_{n,p}^2}.$$ 

We conclude

$$E_f\left[\Pi_{\mathcal{I}, \lambda}(B_{n,p} | \mathcal{D}_n)\right] \leq \exp \left(-|\mathcal{I}| \log \xi + \Xi_6 \lambda s_{n,p}^2 + \Xi_7 \lambda s_{n,p}^2\right)$$

$$\leq \exp \left(-|\mathcal{I}| \log \xi - \Xi_\lambda\right)$$

where we used in the last line that $|\mathcal{I}|$ has a lower bound of order as $\lambda s_{n,p}^2$. For a sufficiently large $\xi$, we obtain $E_f\left[\Pi_{\mathcal{I}, \lambda}(B_{n,p} | \mathcal{D}_n)\right] \leq \alpha (1 - \alpha)^2$ and thus

$$P_f(f \in \tilde{C}(\xi r_{n,p})) \geq 1 - \alpha^2 - \alpha(1 - \alpha) \geq 1 - \alpha. \quad \square$$

### 5.4 Remaining proofs for Section 3

#### 5.4.1 Proof of Corollary 3

Jensen’s and Markov’s inequality yield for $r_{n,p}^2$ from (3.3) that

$$P_f(\mathcal{E}(\hat{f}_\lambda) > r_{n,p}^2 \frac{\Xi_1}{n} + \frac{\Xi_1}{n} \log \frac{2}{\delta}) = P_f\left(\|\mathcal{E}_f[f_{\hat{\theta}_\lambda} | \mathcal{D}_n] - f\|_{L^2(p, X)}^2 > r_{n,p}^2 \frac{\Xi_1}{n} + \Xi_1 \frac{\Xi_1}{n} \log \frac{2}{\delta}\right)$$

$$\leq P_f\left(\mathcal{E}_f[f_{\hat{\theta}_\lambda} - f\|_{L^2(p, X)}^2 | \mathcal{D}_n] > r_{n,p}^2 \frac{\Xi_1}{n} + \Xi_1 \frac{\Xi_1}{n} \log \frac{2}{\delta}\right)$$

$$= P_f\left(\int_{\Xi_1 \frac{\Xi_1}{n} \log(2/\delta)}^{\Xi_1} \Pi_{\lambda}(\|f_{\hat{\theta}_\lambda} - f\|_{L^2(p, X)}^2 > r_{n,p}^2 + t | \mathcal{D}_n) \, dt > \Xi_1 \frac{\Xi_1}{n}\right)$$

$$\leq \frac{n}{\Xi_1} \int_{\Xi_1 \frac{\Xi_1}{n} \log(2/\delta)}^{\Xi_1} E_f\left[\Pi_{\lambda}(\|f_{\hat{\theta}_\lambda} - f\|_{L^2(p, X)}^2 > r_{n,p}^2 + t | \mathcal{D}_n)\right] \, dt.$$

Using Theorem 2 we thus obtain

$$P_f(\mathcal{E}(\hat{f}_\lambda) > r_{n,p}^2 \frac{\Xi_1}{n} + \frac{\Xi_1}{n} \log \frac{2}{\delta}) \leq \frac{2n}{\Xi_1} \int_{\Xi_1 \frac{\Xi_1}{n} \log(2/\delta)}^{\Xi_1} e^{-nt/\Xi_1} \, dt = \delta. \quad \square$$
5.4.2 Proof of Proposition 4

Throughout, denote by $C_i, i = 3, 4, \ldots$ constants only depending on upper bounds for $q, \max_{t\in I} |(d_1, \ldots, d_q)|_\infty$, $|t|_\infty$, $|\beta|_\infty$ and $C_0$.

We will verify that for sufficiently large $n, N \in \mathbb{N}$ there exists a sparse ReLU neural network $g = g_\theta \in \mathcal{G}(C_1[\log_2 n], (p, C_3N, \ldots, C_3N, 1, I)$ with $|I| \leq C_4N[\log_2 n]$ and $|\theta|_\infty \leq 1 \leq B$ such that

$$\|g - f\|_\infty \leq C_3N^{-2p^*/t^*}. \tag{5.9}$$

Both statements of the corollary then follow with $\mathcal{E}(f_{a_2}) \leq \|g_\theta - f\|_{L^\infty([0,1]^q)}^2$ by choosing

$$N = \left( \frac{n}{\log^2(n) \log(pm)} \right)^{t^*/(2p^*+t^*)} \leq n.$$ 

Careful inspection of the proof of Schmidt-Hieber (2020, Theorem 1) reveals that there exists a sparse ReLU neural network $g \in \mathcal{G}(L, \bar{p}, J)$ with weights and shifts absolutely bounded by 1 and

$$L = 3(q - 1) + \sum_{i=0}^{q} \left( 8 + \left( \left\lceil \log_2 n \right\rceil + 5 \right)(1 + \left\lceil \log_2 (t_i \vee \beta_i) \right\rceil) \right),$$

$$\bar{p} = (p, 6rN, \ldots, 6rN, 1), \quad \text{where} \quad r = \max_{i=0,\ldots,q} d_{i+1}(t_i + \left\lceil \beta_i \right\rceil) \quad \text{and}$$

$$|J| \leq \sum_{i=0}^{q} d_{i+1}(141(t_i + \beta_i + 1)^{3+t_i}N(\left\lceil \log_2 n \right\rceil + 6) + 4)$$

such that $(5.9)$ holds, provided $N \geq \max_{i=0,\ldots,q}(\beta_i + 1)^{t_i} \vee (C_0 + 1)e^{t_i}$. Hence, it remains show that $g$ can also be represented as a ReLU neural network in

$$\mathcal{G}(C_1[\log_2 n], (p, C_2n, \ldots, C_2n, 1, I). \tag{5.10}$$

To do this, we employ the embedding properties of network function classes from Schmidt-Hieber (2020, Section 7.1).

Note that $L$ and the upper bound for $|J|$ are independent of $d_0 = p$ and monotonically increasing in $q$ and all entries of $t$ and $\beta$. The same is true for the last $L + 1$ entries of $\bar{p}$. Also, the inner $L$ entries of $\bar{p}$ are of order $N$, $L$ is of order $\log_2 n$ and the upper bound for $|J|$ is of order $N[\log_2 n]$. Using the enlarging and the depth synchronisation properties, $g$ can indeed be written as a ReLU neural network in $(5.10)$. Note that to ensure the depth of the network, we added additional layers after the last hidden layer, instead of right after the input to preserve the order of the sparsity.

5.5 Proofs of the auxiliary results

5.5.1 Proof of Lemma 7

We write $\mathcal{E}_{\eta}(\theta) = \frac{1}{n} \sum_{i=1}^{n} Z_i$ with centred and independent random variables

$$Z_i := (Y_i - f_\theta(X_i))^2 - (Y_i - f(X_i))^2 = -(2\varepsilon_i + f(X_i) - f_\theta(X_i))(f_\theta(X_i) - f(X_i))$$

Since $f$ and $f_\theta$ are bounded by $C$ and $\varepsilon_i$ is sub-Gaussian we have

$$\mathbb{E}_f[Z_i^2] = \mathbb{E}[\left(2\varepsilon_i + f(X_i) - f_\theta(X_i) \right)^2(f_\theta(X_i) - f(X_i))^2] \leq 2(4\sigma^2 + 4C^2)\mathcal{E}(\theta) \leq v$$

and for $k \geq 3$

$$\mathbb{E}_f[(Z_i)^k] \leq \mathbb{E}_f[|2\varepsilon_i + f(X_i) - f_\theta(X_i)|^k|f_\theta(X_i) - f(X_i)|^{k-2}(f_\theta(X_i) - f(X_i))^2]$$

$$\leq (2C)^{k-2}\mathbb{E}_f[|2\varepsilon_i + f(X_i) - f_\theta(X_i)|^k(f_\theta(X) - f(X))^2]$$

$$\leq (2C)^{k-2}\sigma^{k-1}(k!2^{k-1}\sigma^2)^{k-2} + (2C)^k\mathcal{E}(\theta)$$
\[ \leq (2C)^{k-2} k! s^{k-2} (1^{k-2} \vee (2C)^{k-2}) v = \frac{k!}{2} v w^{k-2}. \]

In view of \( \mathbb{E}_f[\mathcal{E}_n(\theta)] = \mathcal{E}(\theta) \), Bernstein’s inequality \cite{Massart2007} inequality (2.21) yields

\[ \mathbb{E} \left[ \exp \left( \lambda (\mathcal{E}_n(\theta) - \mathcal{E}(\theta)) \right) \right] \leq \exp \left( \frac{\nu \lambda^2}{n(1 - w \lambda / n)} \right). \]

The same bound remains true if we replace \( Z_i \) by \( -Z_i \).

### 5.5.2 Proof of Lemma 9

Set \( \eta := |\theta - \tilde{\theta}|_\infty \) and let \( W^{(1)}, \ldots, W^{(L+1)}, b^{(1)}, \ldots, b^{(L)} \) and \( \tilde{W}^{(1)}, \ldots, \tilde{W}^{(L+1)}, \tilde{b}^{(1)}, \ldots, \tilde{b}^{(L)} \) be the weights and shifts associated with \( \theta \) and \( \tilde{\theta} \), respectively. Define \( \tilde{x}^{(l)}, l = 0, \ldots, L + 1 \), analogously to (2.2). We can recursively deduce from the Lipschitz-continuity of \( \sigma \) that for \( l = 2, \ldots, L \):

\[ |x^{(l)} - \tilde{x}^{(l)}|_\infty \leq |W^{(l)} x^{(l-1)} + b^{(l)} - \tilde{W}^{(l)} \tilde{x}^{(l-1)} - \tilde{b}^{(l)}|_\infty \]

\[ \leq \eta |x|_1 + \eta = \eta 2(|x|_1 \vee 1), \]

\[ |x^{(l)}|_\infty \leq |W^{(l)} x^{(l-1)}|_\infty + |b^{(l)}|_\infty \leq p_{l-1} B |x^{(l-1)}|_\infty + B \]

\[ \leq 2p_{l-1}(|x^{(l-1)}|_\infty \vee 1) \quad \text{and} \]

\[ |x^{(l)} - \tilde{x}^{(l)}|_\infty \leq |W^{(l)} x^{(l-1)} + b^{(l)} - \tilde{W}^{(l)} \tilde{x}^{(l-1)} - \tilde{b}^{(l)}|_\infty \]

\[ \leq (|W^{(l)} - \tilde{W}^{(l)}|_\infty |x^{(l-1)}|_\infty + |\tilde{W}^{(l)} (x^{(l-1)} - \tilde{x}^{(l-1)})|_\infty + |b^{(l)} - \tilde{b}^{(l)}|_\infty \]

\[ \leq 2p_{l-1}(|x^{(l-1)}|_\infty \vee 1) + p_{l-1} B |x^{(l-1)} - \tilde{x}^{(l-1)}|_\infty. \]

Therefore,

\[ |x^{(L)}|_\infty \leq (2|\vec{\theta}|_\infty B)^{L-1} (|x^{(1)}|_\infty \vee 1) \leq (2|\vec{\theta}|_\infty B)^{L-1} B 2(|x|_1 \vee 1) \quad \text{and} \]

\[ |x^{(L)} - \tilde{x}^{(L)}|_\infty \leq (|\vec{\theta}|_\infty B)^{L-1} |x^{(1)} - \tilde{x}^{(1)}|_\infty + \eta \sum_{k=1}^{L-1} 2|\vec{\theta}|_\infty (|x^{(L-k)}|_\infty \vee 1) (|\vec{\theta}|_\infty B)^{k-1} \]

\[ \leq \eta 2(|x|_1 \vee 1) \left( (|\vec{\theta}|_\infty B)^{L-1} + L (2|\vec{\theta}|_\infty B)^L \right). \]

Since the clipping function \( y \mapsto (-C) \vee (y \wedge C) \) has Lipschitz constant 1, we conclude

\[ |f_\theta(x) - f_{\tilde{\theta}}(x)| \leq |g_\theta(x) - g_{\tilde{\theta}}(x)| \]

\[ = |x^{(L+1)} - \tilde{x}^{(L+1)}| \]

\[ = |W^{(L+1)} x^{(L)} - \tilde{W}^{(L+1)} \tilde{x}^{(L)}| \]

\[ \leq (|W^{(L+1)} - \tilde{W}^{(L+1)}|_\infty |x^{(L)}|_\infty + |\tilde{W}^{(L+1)} (x^{(L)} - \tilde{x}^{(L)})|_\infty \]

\[ \leq p_{L+1} |W^{(L+1)} - \tilde{W}^{(L+1)}|_\infty |x^{(L)}|_\infty + p_{L+1} |\tilde{W}^{(L+1)} (x^{(L)} - \tilde{x}^{(L)})|_\infty \]

\[ \leq \eta p_{L+1} (2|\vec{\theta}|_\infty B)^{L-1} B 2(|x|_1 \vee 1) + p_{L+1} B \eta 2(|x|_1 \vee 1) \left( (|\vec{\theta}|_\infty B)^{L-1} + L (2|\vec{\theta}|_\infty B)^L \right) \]

\[ \leq \eta 2(|x|_1 \vee 1) (p_{L+1} (2|\vec{\theta}|_\infty B)^{L-1} B + p_{L+1} B \left( (|\vec{\theta}|_\infty B)^{L-1} + L (2|\vec{\theta}|_\infty B)^L \right)) \]

\[ \leq \eta 2(|x|_1 \vee 1) (L + 2 (2|\vec{\theta}|_\infty B)^L). \]

\[ \square \]

### 5.5.3 Proof of Lemma 10

(i) We will show that

\[ \frac{d \rho_{\tau, \eta}}{d \Pi} = C_{\tau} \frac{d \rho_{\tau, \eta}}{d \Pi_{\tau}}. \quad (5.11) \]

from which we can deduce

\[ \text{KL}(\rho_{\tau, \eta}, \Pi) = \int \log \left( \frac{d \rho_{\tau, \eta}}{d \Pi} \right) d \rho_{\tau, \eta} = \int \log \left( \frac{d \rho_{\tau, \eta}}{d \Pi_{\tau}} \right) d \rho_{\tau, \eta} + \log(C_{\tau}) = \text{KL}(\rho_{\tau, \eta}, \Pi_{\tau}) + \log(C_{\tau}). \]
For \([5.11]\) we need to show
\[
\rho_{\mathcal{I},\eta}(A) = \int_A C_{\mathcal{I}}^{-1} \frac{d\rho_{\mathcal{I},\eta}}{d\Pi} d\Pi
\]
for all \(A \in \mathcal{B}_{\mathcal{I}\setminus\emptyset}\). Observe that for the sets
\[
S_{\mathcal{J},\emptyset} := \{ \vartheta \in S_{\mathcal{J}} \mid \vartheta_i \neq 0 \Leftrightarrow i \in \mathcal{J} \}
\]
with \(\emptyset \neq \mathcal{J} \subseteq \{1, \ldots, [\rho]\}\), we have
\[
\Pi_{\mathcal{I}}(S_{\mathcal{J},\emptyset}) = 1. \tag{5.12}
\]
In particular, \([5.12]\) holds for \(\mathcal{J} = \mathcal{I}\). Since also \(\rho_{\mathcal{I},\eta}(S_{\mathcal{I}}) = 1\), no generality is lost in additionally assuming \(A \subseteq S_{\mathcal{I},\emptyset}\). Note how
\[
S_{\mathcal{J},\emptyset} \cap S_{\mathcal{I},\emptyset} = \emptyset \quad \forall \mathcal{J} \neq \mathcal{I}. \tag{5.13}
\]
Combining \([5.12]\) with \([5.13]\) we see that
\[
\int_A \frac{d\rho_{\mathcal{I},\eta}}{d\Pi} d\Pi_{\mathcal{I}} = 0 \quad \forall \mathcal{J} \neq \mathcal{I}.
\]
Therefore,
\[
\rho_{\mathcal{I},\eta}(A) = \int_A \frac{d\rho_{\mathcal{I},\eta}}{d\Pi} d\Pi = \int_A C_{\mathcal{I}}^{-1} \frac{d\rho_{\mathcal{I},\eta}}{d\Pi} d\Pi_{\mathcal{I}}.
\]

(ii) Since \(\rho_{\mathcal{I},\eta}\) and \(\Pi_{\mathcal{I}}\) are product measures, their KL-divergence is equal to the sum of the KL-divergences in each of the \([\rho]\) factors. For factors with index \(i \notin \mathcal{I}\), this is zero, as both factors have all their mass in 0. For factors with index \(i \in \mathcal{I}\), we are comparing
\[
U((\vartheta_{T_i}^+ - \eta_i, \vartheta_{T_i}^+ + \eta_i) \cap [-B, B]) \quad \text{with} \quad U([-B, B]).
\]
The KL-divergence of these distributions is equal to
\[
\log \left( \frac{\mathcal{M}([-B, B])}{\mathcal{M}((\vartheta_{T_i}^+ - \eta_i, \vartheta_{T_i}^+ + \eta_i) \cap [-B, B])} \right) \leq \log \left( \frac{\mathcal{M}([-B, B])}{\mathcal{M}([0, \eta])} \right) = \log(\eta^{-1}2B).
\]
Thus,
\[
\text{KL}(\rho_{\mathcal{I},\eta}, \Pi_{\mathcal{I}}) = \sum_{i \in \mathcal{I}} \text{KL}(U((\vartheta_{T_i}^+ - \eta_i, \vartheta_{T_i}^+ + \eta) \cap [-B, B]), U([-B, B])) \leq |\mathcal{I}| \log(\eta^{-1}2B). \tag*{□}
\]

6 Implementation of the mixing prior distribution

To incorporate sparse networks, Algorithm 1 has to be extended. For a fixed active set \(\mathcal{I}\) we modify the proposal density from \([2.8]\) to
\[
\psi_{\mathcal{I}}((\tau)_i \in \vartheta | \vartheta) = \frac{1}{(2\pi\gamma^2)^{|\mathcal{I}|/2}} \exp \left( -\frac{1}{2\gamma^2} \sum_{i \in \mathcal{I}} (\tau_i - \vartheta_i + \gamma \frac{\partial}{\partial \vartheta_i} R_\eta(\vartheta))^2 \right)
\]
and set \(\tau_i = 0\) for all \(i \notin \mathcal{I}\). The mixture over sparse active sets leads to the conditional proposal density
\[
q(\tau | \vartheta) = \frac{q_-((\tau | \vartheta)) + 2q_+((\tau | \vartheta)) + q_+(\tau | \vartheta)}{4} \mathbb{1}_{\{1 < |\mathcal{I}| < [\rho]\}} + \frac{q_+((\tau | \vartheta)) + 2q_+((\tau | \vartheta))}{3} \mathbb{1}_{\{|\mathcal{I}| = [\rho]\}} + \frac{q_-((\tau | \vartheta)) + 2q_+((\tau | \vartheta))}{3} \mathbb{1}_{\{|\mathcal{I}| = [\rho]\},}
\]
with \(\mathcal{I} = \{i : \vartheta_i \neq 0\}\) and some \(q_-\) and \(q_+\) proposing to remove or add a component, respectively, while \(q_-\) leaves the active set untouched. Specifically, we choose
\[
q_-(\tau | \vartheta) = \psi_{\mathcal{I}}((\tau | \vartheta)), \quad q_-(\tau | \vartheta) = \sum_{i \in \mathcal{I}} w_i^- \psi_{\mathcal{I} \setminus \{i\}}((\tau | \vartheta)) \quad \text{and} \quad q_+(\tau | \vartheta) = \sum_{i \in \mathcal{I}} w_i^+ \psi_{\mathcal{I} \cup \{i\}}((\tau | \vartheta))
\]

20
with
\[ w_i^- = \exp(-|\partial_i|)/\sum_{j \in I} \exp(-|\partial_j|) \quad \text{and} \quad w_i^+ = \tilde{w}_i^+ / \sum_{j \in I^c} \tilde{w}_j^+ \]

where \( \tilde{w}_i^+ = |\{ j \in I^c : |\partial_{j} R_n(\vartheta)| \leq |\partial_{i} R_n(\vartheta)| \}|^2 \). The weights \( \tilde{w}_i^- \) are chosen such that (absolutely) smaller entries have a larger probability of being removed. On the other hand, \( \tilde{w}_i^+ \) are chosen such that components with a large impact (as measured by \( \nabla_\vartheta R_n(\vartheta) \)) on the model have a higher probability of being included. Note that this extension of the algorithm requires no additional computation of \( \nabla_\vartheta R_n(\vartheta) \), as this was already done in the previous MCMC step. Finally, the mixing prior from \( [2.4] \) also has to be accounted for in the acceptance probabilities, leading to

\[ \alpha(\tau, \vartheta) = \min \left\{ 1, \exp \left( -\lambda R_n(\tau) + \lambda R_n(\vartheta) \right) \right\} \]

where with some abuse of notation \( \Pi(\vartheta) \) denotes the probability density of the prior.
