ABSTRACT

Visual Inertial Odometry (VIO) is the problem of estimating a robot’s trajectory by combining information from an inertial measurement unit (IMU) and a camera, and is of great interest to the robotics community. This paper develops a novel Lie group symmetry for the VIO problem and applies the recently proposed equivariant filter. The symmetry is shown to be compatible with the invariance of the VIO reference frame, lead to exact linearisation of bias-free IMU dynamics, and provide equivariance of the visual measurement function. As a result, the equivariant filter (EqF) based on this Lie group is a consistent estimator for VIO with lower linearisation error in the propagation of state dynamics and a higher order equivariant output approximation than standard formulations. Experimental results on the popular EuRoC and UZH FPV datasets demonstrate that the proposed system outperforms other state-of-the-art VIO algorithms in terms of both speed and accuracy.

1 Introduction

Visual Inertial Odometry (VIO) is the problem of determining the trajectory of a robot from a combination of a camera and an inertial measurement unit (IMU). This problem is of enduring interest to the robotics community due to the ubiquity of systems where such sensors are available, including smartphones, VR/AR headsets, racing drones, and more. Solutions to the ‘standard’ variant of VIO, where only a single monocular camera is available, are of particular importance due their wide range of applications. Additionally, the IMU complements the visual data from a monocular camera by providing high-rate motion predictions and making the scale of the system observable, thereby overcoming a key weakness of the camera-only Visual Odometry (VO) problem.

State-of-the-art solutions for VIO are based on either the extended Kalman filter (EKF) or sliding-window optimisation. EKF-based solutions, such as ROVIO [1], OpenVINS [2], and MSCKF [3], are generally less accurate than optimisation-based methods but have lower compute and memory requirements and tend to be used in highly dynamic embedded systems applications such as VR/AR headsets, smartphone applications, aerial vehicles, etc. On the other hand, optimisation-based methods, such as VINS-mono [4] and OKVIS [5], tend to be more accurate than EKF-based methods but require significant compute and memory resources making them appropriate in applications such as automotive, larger robotic systems, etc. The main cause of loss of accuracy for EKF methods relative to optimisation-based methods is associated with the accumulation of linearisation errors. Recent advances in the theory of equivariant systems [6, 7] have shown that exploiting the Lie group symmetries of a system can lead to improved filter designs such as the invariant EKF (IEKF) and the Equivariant Filter (EqF) [8] that minimize linearisation error.

In this paper, we develop a novel Lie group for the VIO problem, and exploit this symmetry in the implementation of an equivariance-based VIO algorithm we term EqVIO. Unlike EKF designs, the EqF back-end of our proposed system has out-of-the-box consistency properties, exact linearisation of the bias-free IMU error dynamics, and a better (higher-order) linearisation error.
The key contributions of this paper are as follows.

- A novel Lie group, the VI-SLAM group, is developed for the VIO problem. This Lie group symmetry is compatible with the reference frame invariance of VIO. Additionally, in contrast to the symmetries explored in prior literature [9], the visual measurement function of VIO is equivariant with respect to the VI-SLAM group.

- The advantages of the VI-SLAM group are clearly demonstrated. Its $SE_2(3)$ component is shown to eliminate linearisation error in the bias-free IMU error dynamics. The novel landmark symmetry, based on $SOT(3)$ components, eliminates second-order approximation error of the visual measurement function by exploiting equivariance. It also improves on and explains the well-known advantages of the inverse-depth parametrisation of landmarks that is core to modern filter performance in VIO algorithms.

- A novel VIO algorithm, EqVIO, is proposed that combines a simple feature-tracking front-end and basic outlier rejection with an equivariant filter implementation. EqVIO is shown to outperform state-of-the-art VIO algorithms in both speed and accuracy on both the popular EuRoC [10] and the challenging UZH FPV [11] datasets. Our implementation of EqVIO is open source and publicly available under a GNU GPLv3 licence [2].

This work is an extension of [12], and improves over the previous version by: providing online calibration of IMU-camera extrinsics; including the robot pose estimation in the EqF directly; detailing the effect of symmetry on the linearisation of IMU error dynamics and visual measurements; and greatly expanding the experimental results to include more thorough comparisons with other state-of-the-art algorithms.

2 Related Work

2.1 Visual Inertial Odometry

Although most VIO solutions rely on constructing a map of the robot’s local environment, the accuracy of this map is not considered important in evaluating system performance, in contrast to traditional Simultaneous Localisation and Mapping (SLAM). Some of the first systems to focus on the problem of trajectory estimation from stereo or monocular vision data, as distinct from general SLAM, were proposed in [13] [14] [15] [16]. An important milestone in the development of VIO systems is the Multi-State Constrained Kalman Filter (MSCKF) [3], which approached the problem by applying a fixed-lag EKF, and, notably, eliminating the estimation of landmark positions from the filter process. This modification resulted in a high speed algorithm for VIO with only linear complexity in the number of landmarks considered. In [17], Konolige et al. considered a system equipped with a stereo camera and an IMU, and employed bundle adjustment to solve the VIO problem. They improved their results by using specialised image features, and discussed the challenge of using traditional image features in self-similar outdoor environments.

Since 2015, the monocular VIO problem specifically has seen substantial interest in the robotics community. Bloesch et al. [1] developed ROVIO: a VIO algorithm that mixes an arbitrary number of cameras with IMU measurements in an iterated EKF framework. In contrast to the majority of EKF-based VIO systems, ROVIO used a ‘direct’ error formulation; that is, rather than obtaining feature coordinates from an image, the image pixel values were considered directly in the system model of the EKF. In parallel, Leutenegger et al. [5] developed OKVIS, which solves monocular and stereo VIO by using non-linear optimisation on a sliding window of ‘keyframes’. Semi-direct Visual Odometry (SVO) [18] used a sparse set of image patches in frame-to-frame optimisation to greatly reduce the presence of outliers and to solve VO at very high speeds. While SVO is not strictly a VIO solution, as it does not use an IMU, Delmerico and Scaramuzza [19] propose two methods to combine the output from SVO with an IMU in a filtering or smoothing framework. Recently, Qin et al. [3] combined a range of modern SLAM techniques to develop VINS-MONO, which performs tightly coupled keyframe optimisation-based VIO with efficient loop closure, and achieves competitive accuracy on popular datasets. Delmerico and Scaramuzza [19] benchmarked a range of state-of-the-art VIO systems. They showed that, generally, the VIO systems optimised for speed and CPU usage suffered from relatively low accuracy, and that many of the popular systems tend to fail on challenging datasets or on limited hardware. OpenVINS [2] is another recent VIO system, which mixes the MSCKF [3] with a traditional EKF and achieves state-of-the-art performance. The primary contribution of OpenVINS was to provide a well-documented open platform for EKF-based VIO research.

In summary, the literature on VIO is split between EKF-based and optimisation-based algorithms. EKF-based algorithms are preferred for their efficiency when computational resources are constrained, but suffer from linearisation error that accumulates and degrades performance over time.

https://github.com/pvangoor/eqvio
2.2 Equivariant Observers for VIO

Equivariant observers are state estimators that exploit available Lie group symmetries of a given problem. Two key examples include the invariant EKF (IEKF) \([6]\) and the Equivariant Filter (EqF) \([8]\). The success of equivariant observers in other robotics problems has led several authors to investigate their application to inertial navigation, SLAM, and VIO. In \([20]\), Barrau and Bonnabel proposed the extended Special Euclidean group \(SE_2(n)\), and show that it can be used to obtain an exact linearisation of IMU error dynamics when the biases are known. This represents a clear improvement over the common representation of IMU states in the SLAM and VIO literature, which uses an on-manifold EKF \([21]\) to obtain a minimal representation of rotation error between quaternions that is analogous to the well-known multiplicative EKF (MEKF) \([22]\).

In the earliest work examining symmetry properties of the SLAM problem, Barrau and Bonnabel \([23]\) proposed a novel class of Lie groups, \(SE_n(m)\), and showed that this is a symmetry suitable for the classical SLAM problem. They further showed that this symmetry is compatible with the reference frame invariance of SLAM, and that the resulting IEKF consequently overcomes the well-known consistency issues of EKF-based SLAM \([24]\). In \([25]\), Zhang et al. performed an observability analysis of the IEKF for SLAM, and compared its performance to a range of other EKFs for SLAM in simulation. Wu et al. \([26]\) then combined \(SE_n(m)\) with the MSCKF concept of \([3]\) to propose an invariant MSCKF for VIO, which they showed to be a consistent filter unlike the original MSCKF. Brossard et al. \([27]\) derived an invariant unscented Kalman filter (IUKF) for monocular SLAM using the Lie group proposed in \([23]\), and outperformed other invariant filters for VIO. A number of other works \([28, 29, 9]\) have also explored applying variants of the IEKF to VIO in an MSCKF framework.

Recently, van Goor et al. \([30]\) developed a novel Lie group for visual SLAM under which the visual measurements of landmarks are equivariant, unlike in the previously explored \(SE_n(n)\) symmetry. The IEKF cannot be directly applied using this symmetry as the Lie group is of a higher dimension than the underlying state space. This issue is overcome by the recent EqF \([8]\), which additionally provides a framework for exploiting the equivariance of a system output function to reduce linearisation error. To the best of our knowledge, there has been no equivariant observer applied to VIO with a symmetry that is compatible with visual measurements prior to this paper and our recent work \([12]\).

2.3 Parametrisations of VIO Landmarks

The representation of the robot pose and environment map are known to have a significant impact on the accuracy of EKF-based SLAM and VIO approaches. In \([31]\), Castellanos et al. identified the inconsistency of the EKF for SLAM when using a straightforward inertial-frame representation of landmarks. They proposed to use a Euclidean body-fixed representation of landmarks instead, and showed that this improved the consistency of the EKF. Another key work in understanding the impact of landmark representations in EKF SLAM is by Civera et al. \([32]\), who proposed the earliest version of the inverse-depth parametrisation of landmarks. The key advantage in this representation is that it is able to represent a large uncertainty in the distance of a landmark from the robot’s initial position using a Gaussian distribution. A more recent version of the inverse-depth parametrisation is presented by Bloesch et al. \([1]\), who adapted the on-manifold EKF approach developed in \([21]\) to obtain a minimal representation of unit vectors on the sphere. While the existing inverse-depth parametrisations have been empirically shown to improve performance over the Euclidean parametrisation, the cause of this improvement is not well characterised.

The discovery of symmetries for visual measurements \([30]\) motivates the development of a new compatible parametrisation.

3 Mathematical Preliminaries

For a comprehensive introduction to smooth manifolds and Lie groups, the authors recommend \([33]\).

3.1 Smooth Manifolds

Given a smooth manifold \(\mathcal{M}\), denote the tangent space at \(\xi \in \mathcal{M}\) by \(T_\xi \mathcal{M}\). The tangent bundle of \(\mathcal{M}\) is written \(T\mathcal{M}\). If \(f : \mathcal{M} \to \mathcal{X}\) is a differentiable function between smooth manifolds, the differential of \(f\) with respect to \(\xi \in \mathcal{M}\) is

\[
D_\xi[f(\xi)]: T_\xi \mathcal{M} \to T_{f(\xi)} \mathcal{X},
\]

\[
u \mapsto D_\xi[f(\xi)]\nu.
\]

When the base point is left unspecified, the differential of \(f\) is a map between tangent bundles \(Df : T\mathcal{M} \to T\mathcal{X}\).

Given \(f : \mathcal{M} \to \mathcal{X}\) and \(g : \mathcal{X} \to \mathcal{X}'\), write the composition \(f \circ g : \mathcal{M} \to \mathcal{X}'\). When \(f\) and \(g\) are linear maps we may also write \(f \cdot g\).

Denote the \(n\)-sphere as

\[S^n := \{x \in \mathbb{R}^n \mid |x| = 1\}.
\]

The 1-sphere \(S^1\) is simply the circle, and forms a Lie group under addition of angles. For any \(n\), the projection onto the sphere \(\pi_{S^n} : \mathbb{R}^n \setminus \{0\} \to S^n\) is defined to be

\[\pi_{S^n}(x) := \frac{x}{|x|}.
\]
3.2 Lie Group Theory

For a Lie group $G$, we write the Lie algebra as $g$. The identity is denoted $id \in G$, and left and right translation are written

$$L_X(Y) := XY, \quad R_X(Y) := YX,$$

respectively. The exponential map is written $exp$, and its inverse (when defined) is the logarithmic map $log$. The Adjoint maps $Ad : G \times g \to g$ and $ad : g \times g \to g$ are defined by

$$Ad_U V = D_L X DR_{X^{-1}} U, \quad ad_U V = [U, V].$$

where $[,]$ is the Lie-bracket on $g$. The wedge and vee operators are linear isomorphisms

$$^\wedge : \mathbb{R}^{\dim g} \to g, \quad ^\vee : g \to \mathbb{R}^{\dim g},$$

satisfying $(u^\vee)^\wedge = u$ for all $u \in g$. When it is not clear from context, we will use a subscript to indicate which Lie group or algebra a particular operation is associated with.

A right group action of a Lie group $G$ on smooth manifold $M$ is a smooth map $\phi : G \times M \to M$ satisfying

$$\phi(XY, \xi) = \phi(Y, \phi(X, \xi)), \quad (2)$$

$$\phi(id, \xi) = \xi, \quad (3)$$

for all $X, Y \in G$ and $\xi \in M$. A left group action is defined similarly, except that the compatibility condition $\phi$ is reversed.

A product Lie group is formed from the combination of multiple existing Lie groups. If $G_1, \ldots, G_n$ are Lie groups, then the product Lie group is

$$G_1 \times \cdots \times G_n := \{(X_1, \ldots, X_n) \mid X_i \in G_i\}, \quad (4)$$

with multiplication, identity, and inverse given by

$$(X_1, \ldots, X_n)(Y_1, \ldots, Y_n) := (X_1Y_1, \ldots, X_nY_n),$$

$$id_{G_1 \times \cdots \times G_n} := (id_{G_1}, \ldots, id_{G_n}),$$

$$(X_1, \ldots, X_n)^{-1} := (X_1^{-1}, \ldots, X_n^{-1}).$$

3.3 Important Lie Groups

The special orthogonal group is the set of 3D rotations,

$$SO(3) := \{R \in \mathbb{R}^{3\times3} \mid R^T R = I_3, \ \det(R) = 1\},$$

$$so(3) := \{\omega^\times \mid \omega \in \mathbb{R}^3\},$$

$$\omega^\times := \begin{pmatrix} 0 & -\omega_3 & \omega_2 \\ \omega_3 & 0 & -\omega_1 \\ -\omega_2 & \omega_1 & 0 \end{pmatrix}.$$

Note that $\omega^\times$ is the unique $3 \times 3$ matrix satisfying $\omega^\times v = \omega \times v$ for all $v \in \mathbb{R}^3$. For any $\omega \in \mathbb{R}^3$, define $(\omega)^{\times}_{so(3)} := \omega^\times$.

The scaled orthogonal transforms are

$$SOT(3) := \left\{ \begin{pmatrix} R & 0 \\ 0 & c \end{pmatrix} \mid R \in SO(3), \ c > 0 \right\},$$

$$SO^\wedge_{sot(3)} := \left\{ (\Omega, s)^\wedge_{sot(3)} \mid \Omega \in \mathbb{R}^3, \ s \in \mathbb{R} \right\},$$

$$SOT^\wedge_{sot(3)} := \left\{ \Omega^\times 0 \mid s \in \mathbb{R} \right\}.$$

Elements of $SOT^\wedge_{sot(3)}$ may be written as $Q = (R_Q, c_Q)$, where $R_Q \in SO(3)$ and $c_Q > 0$. Given $Q \in SOT(3)$ and $p \in \mathbb{R}^3$, we use the shorthand $Qp = c_Q R_Q p$.

The special Euclidean group is the set of 3D rigid body poses,

$$SE(3) := \left\{ \begin{pmatrix} R & x \\ 0 & 1 \end{pmatrix} \mid R \in SO(3), \ x \in \mathbb{R}^3 \right\},$$

$$se(3) := \left\{ (\Omega, v)^\wedge_{se(3)} \mid \Omega, v \in \mathbb{R}^3 \right\},$$

$$sot(3) := \left\{ \Omega^\times 0 \mid v \in \mathbb{R}^3 \right\}.$$
Elements of \( \text{SE}(3) \) may be written as \( P = (R_P, x_P) \), where \( R_P \in \text{SO}(3) \) and \( x_P \in \mathbb{R}^3 \). Given \( P \in \text{SE}(3) \) and \( p \in \mathbb{R}^3 \), we frequently use the shorthand \( Pp := R_Pp + x_Pp \) to denote the standard left group action of \( \text{SE}(3) \) on \( \mathbb{R}^3 \).

The extended special Euclidean group \([20]\) is

\[
\text{SE}_2(3) := \left\{ \left( \begin{array}{ccc} R & x & v \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{array} \right) \mid R \in \text{SO}(3), \ x,v \in \mathbb{R}^3 \right\},
\]

\[
\text{se}_2(3) := \left\{ (\Omega, v, a) \left\wedge \right|_{\text{se}_2(3)} \mid \Omega, v, a \in \mathbb{R}^3 \right\},
\]

\[
(\Omega, v, a) \left\wedge \right|_{\text{se}_2(3)} := \left( \begin{array}{ccc} \Omega^x & v & a \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{array} \right).
\]

Elements of \( \text{SE}_2(3) \) may be written as \( A = (R_A, x_A, v_A) \), or as \( A = (P_A, v_A) \), where \( R_A \in \text{SO}(3) \), \( x_A \in \mathbb{R}^3 \), \( v_A \in \mathbb{R}^3 \), and \( P_A = (R_A, x_A) \in \text{SE}(3) \).

### 4 Problem Description

Choose an arbitrary inertial reference frame \( \{0\} \), and consider a robot equipped with an IMU and a camera, both of which are rigidly attached to the robot’s body. Label the camera frame \( \{C\} \), and identify the IMU frame \( \{I\} \) with the body-fixed frame of the robot \( \{B\} \). The states of the Visual-Inertial SLAM (VI-SLAM) problem are modelled as follows.

- \( P_B := (R_B, x_B) \in \text{SE}(3) \) is the pose of the IMU \( \{B\} \) with respect to the inertial frame \( \{0\} \),
- \( v_B \in \mathbb{R}^3 \) is the linear velocity of the IMU expressed in the inertial frame \( \{0\} \),
- \( b_B = (b^g_B, b^a_B) \in \mathbb{R}^6 \) is the IMU bias (where \( b^g_B \) and \( b^a_B \) are the gyroscope and accelerometer biases, respectively),
- \( T = (R_T, x_T) \in \text{SE}(3) \) is the pose of the camera \( \{C\} \) with respect to the body-fixed frame \( \{B\} \),
- \( p_i \in \mathbb{R}^3 \) are the coordinates of landmark \( i \) in the inertial frame \( \{0\} \).

Figure 1 shows a diagram of the full VI-SLAM configuration.

![Figure 1: A diagram showing the states of visual-inertial SLAM. Note that the IMU biases are excluded here.](image)

Let \( \mathcal{M}^I := \text{SE}(3) \times \mathbb{R}^3 \) denote the navigation state space and define the navigation state \( \xi_B := (P_B, v_B) \in \mathcal{M}^I \). We frequently use the notation \( \xi := (\xi_B, b_B, T, p_i) \) as shorthand for the full VI-SLAM state. To ensure that the visual measurements are always well defined we assume that the system trajectory considered never passes through an exception set,

\[
\mathcal{E} := \left\{ (\xi_B, b_B, T, p_i) \in \mathcal{M}^I \times \text{SE}(3) \times (\mathbb{R}^3)^n \mid (P_B T)^{-1} p_i = 0 \text{ for any } i \right\},
\]

corresponding to all situations where the camera centre coincides with a landmark point. To formalise this, we define the visual inertial SLAM (VI-SLAM) total space

\[
\mathcal{T}_{\text{VI}}^n(3) := \mathcal{M}^I \times \text{SE}(3) \times (\mathbb{R}^3)^n - \mathcal{E}
\]
and consider the visual inertial SLAM problem on $T^\infty_n(3)$. Note that $T^\infty_n(3)$ is an open subset of a smooth manifold and as such is itself a smooth manifold.

### 4.1 VI-SLAM Dynamics

Let the acceleration due to gravity in the inertial frame $\{0\}$ be $ge_3$, where $g \approx 9.81 \text{ m/s}^2$ and $e_3 \in S^2$ is the standard direction of gravity in the inertial frame. Let the measured angular velocity and linear acceleration obtained from the IMU be $(\Omega, a) \in \mathbb{L} := \mathbb{R}^3 \times \mathbb{R}^3$, where $\mathbb{L}$ is the input space. Then the VI-SLAM dynamics $f : \mathbb{L} \rightarrow \mathcal{X}(T^\infty_n(3))$ are

$$
\begin{align*}
\dot{\xi} &= f(\Omega, a)(\xi); \\
\dot{R}_B &= R_B(\Omega - b^0_B) \times, \\
\dot{x}_B &= v_B, \\
\dot{v}_B &= R_B(a - b^0_B) + ge_3, \\
\dot{b}^0_B &= 0, \\
\dot{b}^0_B &= 0, \\
\dot{T} &= 0, \\
\dot{p}_1 &= 0.
\end{align*}
$$

### 4.2 VI-SLAM Measurements

The camera measurements are modelled as $n$ bearing measurements of the landmarks $p_1$ in the camera frame $\{C\}$ on the manifold $\mathcal{N}^n_V(3) := (S^2)^n$ where the superscript "V" stands for visual measurements. The measurement function $h : T^\infty_n(3) \rightarrow \mathcal{N}^n_V(3)$ is given by

$$
\begin{align*}
h(\xi) := (h^1(\xi), \ldots, h^n(\xi)), \\
h^k(\xi_B, b_B, T, p_1) := \pi_{S^2}((P^T_B)^{-1}(p_B)),
\end{align*}
$$

where $\pi_{S^2}$ is defined as in (1). Modelling the bearing measurements directly on the sphere rather than the image plane enables the proposed system to model a wide variety of monocular cameras. Consideration of different camera models is omitted from this paper but is included in the EqVIO software package.

### 4.3 Invariance of Visual Inertial SLAM

Let $e_3$ be the standard gravity direction and define the semi-direct product group

$$S^1 \ltimes e_3 \mathbb{R}^3 := \{ (\theta, x) \mid \theta \in S^1, x \in \mathbb{R}^3 \},$$

with group product, identity and inverse

$$
\begin{align*}
(\theta^1, x^1) \cdot (\theta^2, x^2) &= (\theta^1 + \theta^2, x^1 + R_{e_3}(\theta^1)x^2), \\
1_{S^1 \ltimes e_3 \mathbb{R}^3} &= (0, 0, 0, 1), \\
(\theta, x)^{-1} &= (-\theta, -R_{e_3}(\theta)x),
\end{align*}
$$

where $R_{e_3}(\theta) \in \text{SO}(3)$ is the anti-clockwise rotation of an angle $\theta$ about the axis $e_3$. Then $S^1 \ltimes e_3 \mathbb{R}^3$ is isomorphic to the subgroup

$$\text{SE}_{e_3}(3) := \{ (R, x) \in \text{SE}(3) \mid R e_3 = e_3 \} \subset \text{SE}(3).$$

Define $\alpha : \text{SE}_{e_3} \times T^\infty_n(3) \rightarrow T^\infty_n(3)$ by

$$
\alpha(S, (\xi_B, b_B, T, p_1)) := (S^{-1} P_B, P^T_S v_B, b_B, T, S^{-1}(p_1)).
$$

Then $\alpha$ is a right group action of $\text{SE}_{e_3}(3)$ on $T^\infty_n(3)$. For a given $S \in \text{SE}_{e_3}(3)$, the action $\alpha(S, \cdot)$ represents a change of inertial reference frame from $\{0\}$ to $\{1\}$ where $S$ is the pose of $\{1\}$ with respect to $\{0\}$. Moreover, any change of reference $S \in \text{SE}_{e_3}(3)$ leaves the direction of gravity $e_3$ unchanged.

**Proposition 4.1.** The dynamics (5) and measurements (6) of VI-SLAM are invariant with respect to $\alpha$; that is,

$$
\begin{align*}
f(\Omega, a)(\alpha(S, (\xi_B, b_B, T, p_1))) &= \alpha(S, f(\Omega, a)(\xi_B, b_B, T, p_1)), \\
h(S, (\xi_B, b_B, T, p_1)) &= h(\xi_B, b_B, T, p_1),
\end{align*}
$$

for any $S \in \text{SE}_{e_3}(3)$. 

6
5 Symmetry of VI-SLAM

The VI-SLAM symmetry action proposed in this paper combines the symmetry for IMU dynamics developed in [20] with the VSLAM symmetry developed in [30]. Before discussing the full symmetry group, we discuss the separate symmetries and how they lead to lower linearisation error in the filter development given in the sequel. This section of the paper is written in a more tutorial style to provide the reader with intuition underlying the proposed algorithm.

The advantage of the extended Euclidean symmetry (SE2(3)) used for the navigation states lies in providing a locally linear coordinate representation of the ideal IMU dynamics. That is, for ideal IMU dynamics, then using this representation leads to zero linearisation error during the propagation step of the filter, assuming appropriate Gaussian noise models in local coordinates of course. This property is lost once the bias states and calibration states are added, however, the resulting update still has considerably lower linearisation error in these coordinates than classical formulations. Section 5.1 is based on prior work by Barrau et al. [20].

The advantage of the scaled orthogonal transform (SOT(3)) symmetry used for the landmark states lies in providing a framework in which the measurement linearisation error can be minimized. To make this point clear we analyse the common landmark parametrisations used in the literature and study the linearisation error. This provides a clear theoretical justification for the inverse depth parametrisation that is state-of-the-art in VIO algorithms and goes on to demonstrate that the SOT(3) symmetry leads to lower measurement linearisation error again. The material in Section 5.2 is novel to this paper.

5.1 Symmetry of IMU Dynamics

Let \( f^I : L \to X(M^I) \) denote the IMU dynamics considered in [5] without bias; that is,

\[
\frac{\text{d}}{\text{d}t} f((R, x, v), R, x, v) = \frac{\text{d}}{\text{d}t} (Rf, x, v),
\]

(8)

\[
= (R\dot{\Omega}^f, v_b, R_b a + g e_3).
\]

(9)

Filter designs such as the EKF, on-manifold EKF [21], MEKF [3] and EqF [8] model the evolution of the probability distribution of the system state, given an initial distribution. In each of these filters, the filter’s error coordinates are taken to be normally distributed, and the dynamics of these error coordinates are linearised to propagate the estimated distribution.

Traditional EKF designs model the robot’s attitude through embedded coordinates as a unit quaternion \( q \in H \simeq \mathbb{R}^4 \). This leads to the (over-parametrised) error coordinates,

\[
\varepsilon_{\text{EKF}}(\xi_b, \xi_b) := \begin{pmatrix}
q_b - \hat{q}_b \\
x_b - x_{\xi_b}
\end{pmatrix}.
\]

In the MEKF and the typical on-manifold EKF, the error coordinates are instead defined using the logarithm of SO(3),

\[
\varepsilon_{\text{MEKF}}(\xi_b, \xi_b) := \begin{pmatrix}
\log_{\text{SO}(3)}(R_b R_{\xi_b}^T) \\
x_b - x_{\xi_b}
\end{pmatrix}.
\]

Note that, unlike the EKF, the MEKF has a minimal (9-dimensional) representation of filter error.

In an EqF design, the filter state is part of a Lie group rather than the state space \( M^I \) [8]. Consider the Lie group SE2(3) with right group action \( \varphi : SE_2(3) \times M^I \to M^I \) given by

\[
\varphi(A, \xi_b) := (R_b R_A, x_b + R_b x_A, v_b + R_b v_A),
\]

(10)

where \( A = (R_A, x_A, v_A) \in SE_2(3) \). In this case, SE2(3) and \( M^I \) are isomorphic as smooth manifolds, but the distinction is important for systems on general homogeneous spaces, such as the full VI-SLAM system, where the Lie group may be of a higher dimension than the state space. Choose the origin configuration \( \xi_b = (I_3, 0, 0) \in M^I \), and define a local coordinate chart \( \vartheta^\xi(\xi_b) := \log_{SE_2(3)}(R_b, x_b, v_b) \in \mathbb{R}^9 \). Then the EqF error coordinates are

\[
\varepsilon_{\text{EqF}}(\hat{A}, \xi_b) := \vartheta^\xi(\varphi(A^{-1}, \xi_b)),
\]

(11)

\[
= \log_{SE_2(3)} \begin{pmatrix}
R_b R_A^T & x_b - R R_A^T x_A & v_b - R R_A^T v_A \\
0 & 1 & 0 \\
0 & 0 & 1
\end{pmatrix},
\]

where \( \hat{A} = (R_A, x_A, v_A) \in SE_2(3) \) is the filter state.

Each of these filters model their error coordinates as being drawn from a normal distribution with zero mean and covariance \( \Sigma_b \sim N(0, \Sigma) \), where \( \Sigma \) is the filter’s Riccati matrix. The reported probability distribution of these filters is not guaranteed to
match the true distribution of the state in general, as the propagation of the covariance depends on the linearisation of the error dynamics. For the EqF, however, this linearisation is dependent on the chosen symmetry group $G$, rather than on a chosen set of coordinates as in the EKF. In some special cases, the system dynamics are group affine with respect to the symmetry group $G$, and this results in an exactly linear propagation of the error coordinates [6].

Barrau and Bonnabel [20] showed that the bias-free IMU dynamics are group affine with respect to the action (10) of $\text{SE}_2(3)$. As a result, using the Lie group $\text{SE}_2(3)$, the propagation of bias-free IMU dynamics in the EqF has no linearisation error in normal coordinates. Hence, as long as the initial distribution of the error coordinates is Gaussian, the probability distribution estimated by the EqF will match the true distribution of the state exactly. This is demonstrated in the following example.

Let the initial value of the true state $\xi_B(0) = \exp_{\text{SE}_2(3)}(\eta_0^\wedge)$, where $\eta_0 \in \mathbb{R}^9$ is drawn from the distribution $\mathcal{N}(0, \Sigma_0)$ with

$$
\Sigma_0 = \begin{pmatrix}
0.2^2 I_3 & 0 & 0 \\
0 & 0.01^2 I_3 & 0 \\
0 & 0 & 0.01^2 I_3
\end{pmatrix}.
$$

Initialise each of the filters with this data, and let the angular velocity be $\Omega = (0, 0, 0.1) \text{ rad/s}$ and the linear acceleration be $a = (0.1, 0, 0) \text{ m/s}^2$.

Figure 2: The true distribution of IMU positions at increments of 5 s obtained from integrating the dynamics (9) compared with the estimated distributions from the EKF, MEKF, and EqF.

Figure 2 shows the true and estimated distributions of the IMU position after integrating in 5 s increments. At each time, the true distribution of the system is shown by sampling 2000 particles according to the initial distribution of the state and integrating them independently. The estimated distributions are obtained by integrating the filter equations in 5 s increments, before sampling 2000 points in the error coordinates and mapping them to the estimated state using the filter’s observer state. The figure clearly shows the advantages of applying an appropriate symmetry to the propagation of IMU uncertainty, as the distribution reported by the EqF matches the true distribution far more closely than that of the EKF or MEKF.

An EKF is not an optimal estimator, unlike the linear Kalman filter, due to the accumulation of linearisation errors over time. By exploiting symmetry properties as above, the linearisation error in each step of the EKF can be reduced or even eliminated completely. This leads to improved filter designs that closely reflect the stochastics of the underlying system and provide more accurate state estimates.
5.2 Symmetry of Visual Landmarks

Consider the simplified system of a single landmark \( q \in \mathbb{R}^3 \setminus \{0\} \) in the camera-fixed frame. If the camera-fixed angular and linear velocity are \( \Omega_C, v_C \in \mathbb{R}^3 \), respectively, then the dynamics of the landmark are

\[
\dot{q} = f^\Omega_{(\Omega_C, v_C)}(q) := -\Omega_C \times q - v_C.
\]

The visual measurement of the landmark is

\[
h^\nu(q) = \frac{q}{|q|}
\]

A parametrisation of the landmark is a diffeomorphism \( \varsigma : U \subset \mathbb{R}^3 \rightarrow \mathcal{M}^\nu \subset \mathbb{R}^k \), where \( U \) is an open subset of \( \mathbb{R}^3 \) and \( \mathcal{M}^\nu \) is a smooth 3-dimensional submanifold of \( \mathbb{R}^k \) for some \( k \geq 3 \).

The Euclidean parametrisation was commonly used in early works on visual SLAM \cite{24} and is defined by

\[
\varsigma_{\text{Euc}}(q) := q, \quad \varsigma_{\text{Euc}}^{-1}(z) := z.
\]

The inverse-depth parametrisation, and variants thereof, are used more frequently in recent literature \cite{32,1,2}. An archetypical example is given by

\[
\varsigma_{\text{ID}}(q) := \left( \frac{q}{|q|} \right), \quad \varsigma_{\text{ID}}^{-1}(z) := (I_3 \quad 0_{3 \times 1}) \frac{z}{z_4}.
\]

We introduce a new parametrisation for landmarks with visual measurements by exploiting the \( \text{SOT}(3) \) symmetry actions developed in \cite{30}. The polar parametrisation is a novel parametrisation for visual landmarks, defined by

\[
\varsigma_{\text{SOT}(3)}(q) := \left( -\arccos\left( \frac{e_1^\top q}{|q|} \right), \frac{e_3 \times q}{|q|}, -\log\left( \frac{z}{z_4} \right) \right),
\]

\[
\varsigma_{\text{SOT}(3)}^{-1}(z) := \exp_{\text{SOT}(3)}(\varsigma_{\text{SOT}(3)}^{-1}e_3).
\]

This parametrisation provides normal coordinates for \( \mathbb{R}^3 \) about \( e_3 \) with respect to the right action of \( \text{SOT}(3) \) defined in Lemma \ref{lem:sot3actions}.

**Lemma 5.1.** Let \( \varphi^\nu : \text{SOT}(3) \times \mathbb{R}^3 \setminus \{0\} \rightarrow \mathbb{R}^3 \setminus \{0\} \) and \( \rho^\nu : \text{SOT}(3) \times S^2 \rightarrow S^2 \) be defined by

\[
\varphi^\nu(Q, q) := \varsigma^{-1}_Q R_Q^T q,
\]

\[
\rho^\nu(Q, y) := R_Q^T y.
\]

Then \( \varphi^\nu \) and \( \rho^\nu \) are transitive right group actions, and the visual measurement function \ref{eq:vio} is equivariant with respect to these actions; that is,

\[
h^\nu(\varphi^\nu(Q, q)) = \rho^\nu(Q, h^\nu(q)),
\]

for all \( Q \in \text{SOT}(3) \) and \( q \in \mathbb{R}^3 \setminus \{0\} \).

Let \( \hat{q} \in \mathbb{R}^3 \setminus \{0\} \) be the estimated landmark position and \( q \in \mathbb{R}^3 \setminus \{0\} \) be the true landmark position. Then the parametrised state error is

\[
\varepsilon := \varsigma(q) - \varsigma(\hat{q}),
\]

for a particular parametrisation \( \varsigma \). The true state can be identified in terms of the estimated state and the parametrised state error,

\[
q = \varsigma^{-1}(\varepsilon + \varsigma(\hat{q})).
\]

Linearising the dynamics \ref{eq:3d} and measurement \ref{eq:visual_odometry} in terms of \( \varepsilon \) about \( \varepsilon = 0 \) yields

\[
f^\Omega_{(\Omega, v)}(q) = f_{(\hat{\Omega}, \hat{v})}^\Omega \circ \varsigma^{-1}(\varepsilon + \varsigma(\hat{q})),
\]

\[
= f_{(\hat{\Omega}, \hat{v})(\hat{q}) + D_\theta|\hat{\Omega} f_{(\hat{\Omega}, \hat{v})(\hat{q})} \cdot D_s|\varsigma(q) \varsigma(s)[\varepsilon] + \mu^\nu(q),
\]

\[
h^\nu(q) = h^\nu \circ \varsigma^{-1}(\varepsilon + \varsigma(\hat{q}))
\]

\[
= h^\nu(\hat{q}) + D_p|\varsigma| h^\nu(q) \cdot D_s|\varsigma(q) \varsigma(s)[\varepsilon] + \mu^h(q),
\]

where \( \mu^\nu(q) \) and \( \mu^h(q) \) are the dynamics and measurement linearisation errors, respectively, and capture all higher order terms. In general, both \( \mu^\nu(q) \) and \( \mu^h(q) \) are \( O(|\varepsilon|^2) \), but there are important exceptions. First, the dynamics \ref{eq:3d} are exactly linear in the Euclidean parametrisation \cite{14}, and hence \( \mu^\text{Euc}(q) \equiv 0 \). Second, the equivariant output approximation proposed
in [8] is available when using the polar parametrisation as these are the normal coordinates associated with the action $\varphi^\gamma$ [17]. Specifically, applying [8, Lemma V.3] to this example yields

$$C'_f \varepsilon = \frac{1}{2} (D_E|_id\rho^Y(E, y) + D_E|_id\rho^Y(E, \mathbf{e}_3)) \varepsilon^\wedge_{SOT(3)},$$

$$= \frac{1}{2} \frac{d}{dt}|_{t=0}(\rho^Y(e^{t\varepsilon^\wedge_{SO(3)}} y) + \rho^Y(e^{t\varepsilon^\wedge_{SO(3)}} \mathbf{e}_3)),$$

$$= \frac{1}{2} \frac{d}{dt}|_{t=0}(-R_e e^{t\varepsilon^\wedge_{SO(3)}} y - R_e e^{t\varepsilon^\wedge_{SO(3)}} \mathbf{e}_3),$$

$$= \frac{1}{2} (-\Omega^e_y y - \Omega^e_e \mathbf{e}_3),$$

$$= \frac{1}{2} (y + \mathbf{e}_3) \times \Omega_e,$$

and therefore,

$$C'_f = \frac{1}{2} (y + \mathbf{e}_3) \times 0_{3 \times 1}.$$

This provides an alternative measurement approximation that reduces the output linearisation error to $\mu^h_{SOT(3)}(q) = O(|\varepsilon|^3)$ by exploiting equivariance and using the available true measurement value $y = h(q)$.

To see the effects of different parametrisations on the linearisation errors, let $\tilde{q} = (0, 0, 5)$ and consider the domain

$$U = \{(z \tan(\theta), 0, z) \in \mathbb{R}^3 | z \in (0.1, 10), \theta \in (\frac{\pi}{6}, \frac{5\pi}{6})\}. \tag{20}$$

Let $\Omega_C = (0.0, 0.2, 0.0)$ and $\nu_C = (0.0, 0.0, 0.1)$. This linear and angular velocity is typical of a camera moving forward and turning about the vertical axis of the image.

Figures 3 and 4 show the dynamics and output linearisation errors $\mu^f(q)$ and $\mu^h(q)$, respectively, for each of the parametrisation [14, 15, 16]. Figure 4 also shows the equivariant output approximation [8] in the polar parametrisation. As expected, the Euclidean parametrisation yields no dynamics linearisation error over any part of the domain. Meanwhile, the inverse-depth and polar parametrisations have non-zero dynamics linearisation errors that increase toward the edges of the domain, with the polar parametrisation having a lower maximum linearisation error. On the other hand, for the output linearisation there is a clear advantage to using the inverse-depth or polar over the Euclidean parametrisation. Finally, while the ordinary performance of the inverse-depth and polar parametrisations is similar, the polar parametrisation is able to use the equivariant output approximation which greatly reduces its output linearisation error everywhere in $U$. 

Figure 3: The norm of linearisation error $\|\varepsilon\|$ of the landmark dynamics $\{U\}$ for the Euclidean (14), inverse-depth (15), and polar (16) parametrisations over the domain defined in (20). The Euclidean parametrisation has zero dynamics linearisation error since the dynamics are exactly linear in these coordinates.

Figure 4: The norm of linearisation error (18) of the landmark dynamics (12) for the Euclidean (14), inverse-depth (15), and polar (16) parametrisations over the domain defined in (20). The Euclidean parametrisation has zero dynamics linearisation error since the dynamics are exactly linear in these coordinates.

Figures 3 and 4 show the dynamics and output linearisation errors $\mu^f(q)$ and $\mu^h(q)$, respectively, for each of the parametrisation [14, 15, 16]. Figure 4 also shows the equivariant output approximation [8] in the polar parametrisation. As expected, the Euclidean parametrisation yields no dynamics linearisation error over any part of the domain. Meanwhile, the inverse-depth and polar parametrisations have non-zero dynamics linearisation errors that increase toward the edges of the domain, with the polar parametrisation having a lower maximum linearisation error. On the other hand, for the output linearisation there is a clear advantage to using the inverse-depth or polar over the Euclidean parametrisation. Finally, while the ordinary performance of the inverse-depth and polar parametrisations is similar, the polar parametrisation is able to use the equivariant output approximation which greatly reduces its output linearisation error everywhere in $U$. 

Figure 3: The norm of linearisation error $\|\varepsilon\|$ of the landmark dynamics $\{U\}$ for the Euclidean (14), inverse-depth (15), and polar (16) parametrisations over the domain defined in (20). The Euclidean parametrisation has zero dynamics linearisation error since the dynamics are exactly linear in these coordinates.

Figure 4: The norm of linearisation error (18) of the landmark dynamics (12) for the Euclidean (14), inverse-depth (15), and polar (16) parametrisations over the domain defined in (20). The Euclidean parametrisation has zero dynamics linearisation error since the dynamics are exactly linear in these coordinates.

Figures 3 and 4 show the dynamics and output linearisation errors $\mu^f(q)$ and $\mu^h(q)$, respectively, for each of the parametrisation [14, 15, 16]. Figure 4 also shows the equivariant output approximation [8] in the polar parametrisation. As expected, the Euclidean parametrisation yields no dynamics linearisation error over any part of the domain. Meanwhile, the inverse-depth and polar parametrisations have non-zero dynamics linearisation errors that increase toward the edges of the domain, with the polar parametrisation having a lower maximum linearisation error. On the other hand, for the output linearisation there is a clear advantage to using the inverse-depth or polar over the Euclidean parametrisation. Finally, while the ordinary performance of the inverse-depth and polar parametrisations is similar, the polar parametrisation is able to use the equivariant output approximation which greatly reduces its output linearisation error everywhere in $U$. 

Figure 3: The norm of linearisation error $\|\varepsilon\|$ of the landmark dynamics $\{U\}$ for the Euclidean (14), inverse-depth (15), and polar (16) parametrisations over the domain defined in (20). The Euclidean parametrisation has zero dynamics linearisation error since the dynamics are exactly linear in these coordinates.

Figure 4: The norm of linearisation error (18) of the landmark dynamics (12) for the Euclidean (14), inverse-depth (15), and polar (16) parametrisations over the domain defined in (20). The Euclidean parametrisation has zero dynamics linearisation error since the dynamics are exactly linear in these coordinates.
5.3 Composite Symmetry for VI-SLAM

Define the VI-SLAM Group to be

\[ \text{SLAM}_{n}^{VI}(3) := \text{SE}_{2}(3) \times \text{SOT}(3)^{n}. \]  

(21)

This is a product Lie group in the sense of (4). This group captures the symmetries that are fundamental to the VIO system: \( \text{SE}_{2}(3) \) for the IMU dynamics and \( \text{SOT}(3)^{n} \) for \( n \) landmarks with visual measurements. In a practical implementation, however, it is also necessary to consider the extrinsic calibration parameters and IMU biases, for which an \( \text{SE}(3) \) and an \( \mathbb{R}^{6} \) symmetry can be used, respectively. To this end, define the extended direct product group

\[ G := \text{SE}_{2}(3) \times \mathbb{R}^{6} \times \text{SE}(3) \times \text{SOT}(3)^{n}, \]

\[ \simeq \text{SLAM}_{n}^{VI}(3) \times \mathbb{R}^{6} \times \text{SE}(3). \]  

(22)

We denote a typical element as \( X = (A, \beta, B, Q_{i}) \in G \), and frequently use the shorthand \( (A, \beta, B, Q_{i}) \).

Lemma 5.2. The map \( \phi : G \times \tau_{n}^{VI}(3) \rightarrow \tau_{n}^{VI}(3) \) defined by

\[ \phi((A, \beta, B, Q_{i}), (\xi_{b}, b_{B}, T, p_{i})) := (\varphi^{b}(A, \xi_{b}), b_{B} + \beta, P_{A}^{-1}TB, P_{B}^{T}BQ_{i}^{-1}T^{-1}P_{B}^{-1}(p_{i})), \]

(23)

where \( \varphi^{b} \) is defined as in (10), is a transitive right group action.

Lemma 5.3. The group action \( \phi \) (23) is compatible with the VI-SLAM invariance \( \alpha \) (7); that is,

\[ \phi(X, \alpha(S, \xi)) = \alpha(S, \phi(X, \xi)), \]

for all \( \xi \in \tau_{n}^{VI}(3) \), \( S \in \text{SE}_{2}(3) \), and \( X \in G \).

Lemma 5.4. The map \( \rho : G \times \mathcal{N}_{n}(3) \rightarrow \mathcal{N}_{n}(3) \) defined by

\[ \rho((A, \beta, B, Q_{i}), (y_{i})) := (R_{Q_{i}}^{T}y_{i}), \]

(24)

is a right group action. Additionally, the measurement function (9) is equivariant with respect to the actions \( \phi \) (23) and \( \rho \); that is,

\[ h(\phi(X, \xi)) = \rho(X, h(\xi)), \]

for all \( X \in G \) and \( \xi \in \tau_{n}^{VI}(3) \).
Overall, the structure presented provides a complete symmetry of the VIO dynamics and measurement. This is summarised by the diagram

\[
\begin{array}{ccc}
\mathcal{T}_n^{VI}(3) & \xrightarrow{g_0} & \mathcal{X}_n^{VI}(3) \\
\phi_X & \searrow & \rho_X \\
\mathcal{T}_n^{VI}(3) & \xrightarrow{g_0} & \mathcal{X}_n^{VI}(3)
\end{array}
\]

which commutes for any \( X \in G \) and \( S \in \text{SE}_n(3) \).

6 Equivariant Filter for VIO

While the performance of an EKF for VIO depends largely on what coordinates are chosen, the performance of an EqF depends instead on the symmetry used. The VI-SLAM symmetry yields a few key advantages:

The EqF equipped with the VI-SLAM symmetry is a consistent estimator for VIO. In Lemma 6.1, Lemma 5.2 is used to lift the system dynamics from the state space manifold to the chosen symmetry group \( G \), and the resulting lift \( \Lambda \) is shown to be invariant to the reference frame transformation \( \alpha \) \([7]\). Then, since both the group action \( \phi \) \([23]\) and the lift \( \Lambda \) \([25]\) are compatible with \( \alpha \) \([7]\) (c.f. Lemmas \([5, 6]\), the proposed EqF naturally also respects the invariance. Specifically, if the Riccati matrix \( \Sigma \) of the EqF is treated as a covariance, then the Fisher information \( \Sigma^{-1} \) is non-increasing along the unobservable directions spanned by the differential of \( \alpha \), and therefore the EqF is consistent by \([34, \text{Theorem 2}]\).

The EqF uses a higher order (more precise) output approximation than that available to the EKF. The system output function is approximated by an EKF, it has no second order error terms. That is,

\[
y - h(\hat{\xi}) = C_t^* \varepsilon + O(|\varepsilon|^3),
\]

where \( y \) is the true measurement, \( \hat{\xi} \) is the EqF state estimate, and \( \varepsilon \) is the local error coordinates of the EqF.

6.1 Lifted Dynamics and Consistency

The existence of a transitive action by the VI-SLAM group on the VI-SLAM manifold guarantees the existence of a lift for the system dynamics \([5]\) in the sense of \([7]\). Although \([7]\) provides a constructive algorithm to build lifts, in practice it is easiest to guess the lift and then prove it satisfies the required conditions.

**Lemma 6.1.** The map \( \Lambda : \mathcal{T}_n^{VI}(3) \times (\mathbb{R}^3 \times \mathbb{R}^3) \to g \), given by

\[
\Lambda((\xi_b, b, T, p_i), (\Omega, a)) := \begin{pmatrix} (\Omega, R_b^T v, a)_{\text{SE}(3)}, & 0, & (\Omega_C, v_C)_{\text{SE}(3)} \\ \left(\Omega_C + q_i^x v_C [q_i^x \|q_i^x\|^2, q_i^y \|q_i^y\|^2]\right) \end{pmatrix}, \quad q_i := (PT_C)^{-1}(p_i), \quad (\Omega_C, v_C)_{\text{SE}(3)} := \text{Ad}_{T^{-1}}(\Omega, R_b^T v)_{\text{SE}(3)},
\]

is a lift \([7]\) of the system dynamics \([5]\). That is,

\[
D_E \cdot \text{id}_E \cdot ((\xi_b, b, T, p_i), (\Omega, a)) = f(\Omega, a)((\xi_b, b, T, p_i))
\]

Moreover, \( \Lambda \) is invariant with respect to the action \( \alpha \) \([7]\); i.e.

\[
\Lambda(\alpha(S, (\xi_b, b, T, p_i)), (\Omega, a)) = \Lambda(\xi_b, b, T, p_i), (\Omega, a))
\]

for all \( S \in \text{SE}_n(3)(3) \).

**Proof.** The proof that \( \Lambda \) satisfies the lift condition \([26]\) closely follows the proof of \([30, \text{Lemma 4.4}]\), and the invariance of \( \Lambda \) to \( \alpha \) is straightforward. Both have been omitted to save space.
6.2 Origin Choice and Local Coordinates

Let \( \hat{\xi} = (\hat{\xi}_b, \hat{b}, \hat{T}, \hat{p}_i) \in \mathcal{T}_n^{VI}(3) \) denote the chosen, fixed origin configuration, with \( \hat{p}_i := \hat{P}_b \bar{T}_i \) for every \( i \). For generality, we leave the remaining terms \( \hat{\xi}_b, \hat{b}, \hat{T} \) arbitrary.

Define the map \( \vartheta : \mathcal{U}_B \subset \mathcal{T}_n^{VI}(3) \rightarrow \mathbb{R}^{21+3n} \) by

\[
\vartheta(\hat{\xi}_b, b, T, p_i) := \begin{pmatrix}
\log_{\text{SE}(3)}(\hat{R}_B^+ R_B, \hat{R}_B^+(x_B - \hat{x}_B), \hat{R}_B^+(v_B - \hat{v}_B))^\top \\
\hat{b}_B - \hat{b}_A \\
\log_{\text{SE}(3)}((P_1 T_1)^{-1}(P_1 T))^\top \\
\varsigma_{\text{SOT}}(3)((P_1 T_1)^{-1}(p_1)) \\
\vdots \\
\varsigma_{\text{SOT}}(3)((P_1 T_1)^{-1}(p_n))
\end{pmatrix},
\]

to be the coordinate chart for \( \mathcal{T}_n^{VI}(3) \) about \( \hat{\xi} \), where \( \mathcal{U}_B \) is a large neighbourhood of \( \hat{\xi} \) and \( \varsigma_{\text{SOT}}(3) \) is the polar parametrisation \([16]\). Then \( \vartheta \) provides normal coordinates for \( \mathcal{T}_n^{VI}(3) \) about \( \hat{\xi} \) with respect to the action \( \phi \).

6.3 EqF Dynamics

Denote the true state of the system \( \xi = (\xi_b, b, T, p_i) \in \mathcal{T}_n^{VI}(3) \), let the input signals be \((\Omega, a) \in \mathbb{R}^3 \times \mathbb{R}^3\), and denote the measurements as \( y = h(\xi) \).

Let \( \hat{X} = (\hat{A}, \hat{\beta}, \hat{B}, \hat{Q}_i) \in \mathbf{G} \) be the observer state and \( \Sigma \in \mathbb{S}_+(21 + 3n) \) be the Riccati matrix, where \( \mathbb{S}_+(k) \) denotes the set of positive definite \( k \times k \) matrices. Define \( \hat{A}_i, \hat{B}_i, \hat{C}_i^* \) to be the state, input, and equivariant output matrices of the EqF as defined in \([8]\), respectively, and let \( D_{E|\text{id}||\Phi_1}(E)^\dagger \) be a fixed right-inverse of \( D_{E|\text{id}||\Phi_1}(E) \). Then the EqF dynamics \([8]\) are defined to be

\[
\hat{\dot{X}} = \hat{X} \Lambda(\phi(\hat{X}, \hat{\xi}), (\Omega, a)) - \Delta \hat{X}, \\
\Delta = D_{E|\text{id}||\Phi_1}(E)^\dagger \cdot D_{E|\text{id}||\Phi_1}(\xi)^{-1} \Sigma C_i^* T_i^{-1} (y - h(\hat{\xi})), \\
\hat{\Sigma} = \hat{A}_i \Sigma + \Sigma \hat{A}_i^\top + M_e + B_i M_i^m B_i^\top - \Sigma C_i^* T_i^{-1} N_i^{-1} C_i^* \Sigma,
\]

where \( \Delta \in \mathfrak{g} \) is the EqF correction term, and

- \( \Sigma(0) = \Sigma_0 \in \mathbb{S}_+(21 + 3n) \) is the initial Riccati gain,
- \( M_e \in \mathbb{S}_+(21 + 3n) \) is the state gain,
- \( M_i^m \in \mathbb{S}_+(6) \) is the input gain,
- \( N_i \in \mathbb{S}_+(2n) \) is the output gain,

following their descriptions in \([8]\).

At any time, the EqF state estimate is given by

\[
\hat{\xi} = (\hat{\xi}_b, \hat{b}, \hat{T}, \hat{p}_i) := \phi(\hat{X}, \hat{\xi}).
\]

7 Experimental Results

The EqF equations \((28)\) are discretised and implemented in c++17 using the Eigen matrix library \([35]\). Visual measurements of landmarks are obtained using GIFT \([30, 36]\) to identify and track image features. We refer to the resulting system as \textit{EqVIO}. The four key steps in EqVIO are

- **Features**: The number of features tracked is kept to a fixed limit that can be set by the user. When the number of features that are successfully being tracked falls below a chosen threshold, new image features are identified.
- **Preprocessing**: If a feature is unable to be tracked or is identified as an outlier, the corresponding landmark is removed from the state. If any new features have been identified, they are added to the state.
- **Propagation**: Upon receiving an IMU signal, the EqF state and Riccati equation are integrated without the correction terms.
- **Update**: After augmenting the state and removing outliers, the EqF state and Riccati equation are integrated exclusively with the correction terms.

Figure \(\text{S}\) provides an overview of the system components and how each of the steps are linked.
Figure 5: An overview of EqVIO as a system. The key components can be split into the front-end (GIFT) and the back-end (EqF).

7.1 Performance Comparisons

We compared the performance of EqVIO to other VIO systems on two popular public datasets: EuRoC [10] and UZH FPV [11]. Table 1 lists the algorithms considered along with information about the back-end and front-end systems used, including GFFT [37], LKT [38], FAST [39], ORB [40], and BRISK [41].

Where stated, the algorithm performance results have been obtained from the recent benchmark study by Delmerico and Scaramuzza [19]. Otherwise, the algorithms were compiled using the suggested default configuration and run on an Ubuntu 20.04 desktop computer equipped with an AMD Ryzen 7 3700X 8-Core processor and 16 GB memory. The tuning parameters of the algorithms were changed between the EuRoC and UZH FPV datasets, but kept constant across all sequences in those datasets. Additional system capabilities are including loop closure and map reuse were disabled where relevant to ensure a fair comparison between algorithms.

Table 2 lists the root mean square error (RMSE) of the position estimates of each of the systems in Table 1 on the EuRoC dataset. EqVIO achieves the best performance in many of the sequences, and also achieves the best mean performance. Additionally, Table 3 lists the processing time taken per frame for each of the algorithms tested on the authors’ desktop. On average, EqVIO is faster than the next fastest algorithm by a factor of 2.1 on the EuRoC dataset.

Table 4 lists the RMSE of the position estimates for a subset of the systems in Table 1 on some sequences from the UZH FPV dataset. To ensure a fair comparison, the sequences considered here are those for which OpenVINS has publicly listed tuning parameters at the time of writing. The default tuning parameters were used for ROVIO, and its performance could perhaps be improved with tuning specific to the challenging dataset. The tuning parameters for VINS-Mono were taken from those used in VINS-Stereo (https://github.com/rising-turtle/VINS-Stereo) but with the second camera disabled. As in the EuRoC dataset, EqVIO achieves the best performance in many of the sequences and the best mean performance. Additionally, from Table 5 it is clear that EqVIO is also significantly faster than any of the other algorithms considered. On average, EqVIO is faster than the next fastest algorithm by a factor of 6.0 on the UZH FPV dataset. EqVIO achieved an average processing speed of 338 Hz over all the sequences, and a maximum processing speed of 400 Hz on indoor_45_13.

7.2 Example Performance Details

In addition to the experiments comparing EqVIO’s performance with other state-of-the-art algorithms, we collected data to evaluate and verify the system’s performance. We provide examples of these additional results on the EuRoC sequence V2_01.

14
This paper presents and develops EqVIO: a novel system for visual inertial odometry based on the recently proposed equivariant filter. A new Lie group, the VI-SLAM group, is developed for the VIO problem. It is shown that this symmetry is compatible with the well-known reference frame invariance of VIO, and that therefore the resulting EqF is a naturally consistent estimator. The VI-SLAM group incorporates the extended special Euclidean group $\text{SE}_2(3)$ proposed in [20], leading to exact linearisation of the error dynamics associated with the navigation states. The VI-SLAM group also takes advantages of the SOT(3) sym-

Appendix

Proof of Proposition [4.7] Let $S \in \text{SE}_3(3)$, $\xi = (\xi_b, b_b, T, p_i) \in \mathcal{T}'n(3)$, and $(\Omega, a) \in \mathbb{L}$ be arbitrary. Then compute

\[
\begin{align*}
    f_{(\Omega,a)}(\alpha(S, (\xi_b, b_b, T, p_i))) &= f_{(\Omega,a)}((S^{-1}P_b, R_S^T v_b, b_b), T, S^{-1}(p_i)), \\
    &= ((R_S^T R_b)(\Omega - b_b^\Omega)^*, (R_S^T v_b), (R_S^T R_b)(a - b_b^\alpha) + g e_3, \\
    &\quad 0, 0, 0), \\
    &= (R_S^T (R_b(\Omega - v^\Omega)), R_S^T v_b, R_S^T (R_b(a - b_b^\alpha) + g e_3), \\
    &\quad 0, 0, 0), \\
    &= d \alpha_S f_{\Omega,a}(\xi_b, b_b, T, p_i),
\end{align*}
\]

where the second-last line follows from $R_S^T e_3 = e_3$. This shows that, indeed, $f$ is invariant with respect to the action $\alpha$. To show the invariance of $h$, it is sufficient to show the invariance of the component functions $h^k$ defined in (6). One has that

\[
\begin{align*}
    h^k(\alpha(S, (\xi_b, b_b, T, p_i))) &= h^k(((S^{-1}P_b, R_S^T v_b, b_b^\alpha, b_b^\Omega), T, S^{-1}(p_i)), \\
    &= \pi_{S^2} ((S^{-1}P_bT)^{-1}(S^{-1}(p_i))), \\
    &= \pi_{S^2} ((P_bT)^{-1}S^{-1}(p_i)), \\
    &= \pi_{S^2} ((P_bT)^{-1}(p_i)), \\
    &= h^k(\xi_b, b_b, T, p_i).
\end{align*}
\]

This completes the proof.

Proof of Lemma [5.1] It is straightforward to see that $\varphi^\nu$ and $\rho^\nu$ are indeed right group actions. To see the equivariance of $h^\nu$, let $Q \in \text{SOT}(3)$ and $q \in \mathbb{R}^3 \setminus \{0\}$ be arbitrary. Then,

\[
\begin{align*}
    h^\nu(\varphi^\nu(Q, q)) &= h^\nu(c_Q^{-1} R_Q^T q), \\
    &= \frac{c_Q^{-1} R_Q^T q}{|c_Q^T R_Q^T q|}, \\
    &= \frac{c_Q^{-1} R_Q^T q}{c_Q^{-1} |R_Q^T q|}, \\
    &= R_Q^T \frac{q}{|q|}, \\
    &= \rho^\nu(Q, h^\nu(q)),
\end{align*}
\]

as required.
Proof of Lemma 5.2. Let \( \xi = (\xi_b, b_b, T, p_t) \in T_{n1}^{(3)} \) and \( X_1 = (A_1, \beta_1, B_1, Q_1) \), \( X_2 = (A_2, \beta_2, B_2, Q_2) \in G \) be arbitrary. Then,

\[
\phi(X_2, \phi(X_1, \xi)) = \phi(X_2, (\varphi^B(A_1, \xi_b), b_b + \beta_1, P_{A_1}^{-1}TB_1, P_bTB_1Q_{A_1}^{-1}T^{-1}P_{A_1}^{-1}(p_t))),
\]

\[
= \phi((\varphi^B(A_1)A_2, \xi_b), b_b + \beta_1 + \beta_2, P_{A_1}^{-1}P_{A_2}^{-1}(P^{-1}_{A_1}TB_1)B_2, P_bP_{A_2}P_{A_1}^{-1}TB_1B_2Q_{A_1}^{-1}(P^{-1}_{A_1}TB_1)^{-1}P_{A_2}^{-1}(p_t)),
\]

\[
= \phi((\varphi^B(A_1A_2)B, \xi_b), b_b + \beta_1 + \beta_2, (P_{A_1}P_{A_2})^{-1}T(B_1B_2), P_bTB_1B_2Q_{A_2}^{-1}B_1^{-1}T^{-1}P_{A_2}^{-1}P_{A_1}^{-1}P_{A_1}^{-1}T^{-1}P_{A_2}^{-1}(p_t)),
\]

\[
= \phi(X_1, X_2, \xi).
\]

This shows that the compatibility condition (2) is satisfied. For the identify condition (3), compute

\[
\phi(id_G, \xi) = \phi((I, 0, I_4, (I_4)), (\xi_b, b_b, T, p_t)),
\]

\[
= (\varphi^B(I_5, \xi_b), b_b + 0, I_4TT_4, P_bTT_4I_4^{-1}T^{-1}P_{A_1}^{-1}(p_t)),
\]

\[
= (\xi_b, b_b, p_t).
\]

Then, indeed, \( \phi \) is a group action. Finally, to see that \( \phi \) is transitive, let \( \xi^1, \xi^2 \in T_{n1}^{(3)} \) be arbitrary, and let \( X = (A, \beta, B, Q) \in G \) such that

\[
P_A = (P_{A_1}^{-1})^{-1}P_{A_2}^{-1},
\]

\[
u_A = (R_{A_1}^{-1}T'v_A - v_{b_1}),
\]

\[
\beta = b_{b_2} - b_{b_1},
\]

\[
B = (P_{A_1}^{-1}T')^{-1}(P_{A_2}^{-1}T^2),
\]

\[
Q_i((P_{A_1}^{-1}T')^{-1}p_i^2) = (P_{A_1}^{-1}T')^{-1}p_i^2.
\]

Then it is straightforward to see that \( \phi(X, \xi^1) = \xi^2 \). This completes the proof.

\[
\]

Proof of Lemma 5.3. Let \( \xi = (\xi_b, b_b, T, p_t) \in T_{n1}^{(3)}, S \in \text{SE}_n^{(3)} \) and \( X = (A, \beta, B, Q) \in G \) be arbitrary. Then,

\[
\phi((A, \beta, B, Q)), \alpha(S, (\xi_b, b_b, T, p_t)) = \phi((A, \beta, B, Q)), (S^{-1}P_A, R_S^{-1}v_b, b_b, T, S^{-1}(p_t)),
\]

\[
= (S^{-1}P_A, R_S^{-1}v_b + R_S^{-1}R_Av_A, b_b + \beta, A^{-1}TB, S^{-1}P_ATBQ_S^{-1}(S^{-1}P_A)^{-1}S^{-1}(p_t)),
\]

\[
= (S^{-1}(P_AP_A), R_S^{-1}(v_b + R_Av_A), b_b + \beta, A^{-1}TB, S^{-1}P_ATBQ_S^{-1}P_{A_1}^{-1}(p_t)),
\]

\[
= \alpha(S, (P_AP_A, v_b + R_Av_A, b_b + \beta, A^{-1}TB, P_ATBQ_S^{-1}P_{A_1}^{-1}(p_t)),
\]

\[
= \alpha(S, \phi(X, \xi)),
\]

as required.
Proof of Lemma 5.4: It is trivial to see that \( \rho \) is a group action. To show the equivariance of \( h \), one examines the component measurement functions \( h^k \). Let \( X = (A, \beta, B, Q_1) \in G \) and \( \xi = (\xi_b, b_h, T, p_i) \in T^h(3) \). Then one has

\[
\begin{align*}
    h^k(\phi((A, \beta, B, Q_1), (\xi_b, b_h, T, p_i))) &= h^k(\phi^0(A, \xi_b), b_h + \beta, P_A^{-1}TB, P_aTBQ^{-1}_bT^{-1}P_a^{-1}(p_i)), \\
    &= \pi_{S^2}((P_bPA)^{-1}(P_bTBQ^{-1}_kT^{-1}P_b^{-1}(p_k))), \\
    &= \pi_{S^2}((P_bPA_P^1TB)^{-1}(P_bTBQ^{-1}_kT^{-1}P_b^{-1}(p_k))), \\
    &= \pi_{S^2}(Q_a^{-1}T^{-1}P_b^{-1}(p_k)), \\
    &= \frac{c_{Q_b}^{-1}R_{Q_b}^T}{[c_{Q_b}^{-1}R_{Q_b}^T]}(p_k) \\
    &= R_{Q_b}^T[p_k].
\end{align*}
\]

It follows that

\[
\begin{align*}
    h(\phi((A, \beta, B, Q_1), (\xi_b, b_h, T, p_i))) &= (h^1(\phi((A, \beta, B, Q_1), (\xi_b, b_h, T, p_i))), \ldots, h^n(\phi((A, \beta, B, Q_1), (\xi_b, b_h, T, p_i)))), \\
    &= (R_{Q_b}^TR_{Q_b}^T(\xi_b, b_h, T, p_i), \ldots, R_{Q_b}^T(\xi_b, b_h, T, p_i)), \\
    &= \rho((A, \beta, B, Q_1), h(\xi_b, b_h, T, p_i)),
\end{align*}
\]

as required.
