Abstract
We consider a single source-destination pair, where information updates (in short, updates) arrive at the source at arbitrary time instants. For each update, its size, i.e. the service time required for complete transmission to the destination, is also arbitrary. At any time, age of information (AoI) is equal to the difference between the current time, and the arrival time of the latest update (at the source) that has been completely transmitted (to the destination). AoI quantifies the staleness of the update (information) at the destination. The goal is to find a causal (i.e. online) scheduling policy that minimizes the time-average of AoI, where the possible decisions at any time are i) whether to preempt the update under transmission upon arrival of a new update, and ii) if no update is under transmission, then choose which update to transmit (among the available updates).

In this paper, we propose a causal policy called SRPT\(^+\) that at each time, i) preempts the update under transmission if a new update arrives with a smaller size (compared to the remaining size of the update under transmission), and ii) if no update is under transmission, then begins to transmit the update for which the ratio of the reduction in AoI upon complete transmission (if not preempted in future) and the remaining size, is maximum. We characterize the performance of SRPT\(^+\) using the metric called the competitive ratio, i.e. the ratio of the average AoI of causal policy and the average AoI of an optimal offline policy (that knows the entire input in advance), maximized over all possible inputs. We show that the competitive ratio of SRPT\(^+\) is at most 4.

Further, we propose a simpler policy called SRPT\(^L\), that i) preempts the update under transmission if a new update arrives with a smaller size (compared to the remaining size of the update under transmission), and ii) if no update is under transmission, then begins to transmit the update with the latest arrival time. We show that the competitive ratio of SRPT\(^L\) is at most 29.

1 Introduction

Online scheduling is a classical problem, where jobs with different processing requirements (sizes) arrive at arbitrary times, and an algorithm has to make its scheduling decisions using only the causal information. Typical performance metrics for which online scheduling problem has been considered are flow time [21, 22, 10, 2], completion time [8, 15], makespan [7, 6], co-flow [23, 1, 5, 9], and several others. For many of these problems, either an optimal or near optimal algorithms are known. For example, the shortest remaining processing time (SRPT) algorithm is optimal for minimizing the flow time for a single server [21], while its multi-server counterpart has the optimal (order-wise) competitive ratio [16].

Even though the mentioned performance metrics model a wide variety of problem settings, more modern paradigms such as internet-of-things, cyber-physical systems, etc., require a
metric that can capture information timeliness. Information timeliness refers to the frequency at which fresh information is received at a controller/monitor. A compelling use case is a smart car, that is equipped with multiple sensors and a centralized monitor. Updates are generated at each sensor continuously that are needed to be made available at the monitor without being too ‘old’. An elegant and popular metric to capture information timeliness is known as the age of information (AoI) \cite{Dai13, Kaul12}, which at any time is equal to the time elapsed since the generation time of the latest update of the source that has been completely transmitted to the monitor (destination). The effective metric is then the time-average of the AoI (in short, average AoI). We illustrate AoI plot for a particular example (Example 1) in Figure 1.

\begin{center}
    \begin{figure}
        \centering
        \includegraphics[width=\textwidth]{AoI_plot.png}
        \caption{Age of information (AoI) depends on the generation time of latest completely transmitted update. Here, $G$ denotes update generation, while $C$ denotes transmission completion.}
    \end{figure}
\end{center}

\textbf{Example 1.} Let three updates are generated at the source, at time $g_1 = 0$, $g_2 = 2$ and $g_3 = 4$, respectively. Let an algorithm completely transmits the three updates by time $r_1 = 1$, $r_2 = 3$ and $r_3 = 5$, respectively. As shown in Figure 1 at any time $t$ in interval $[r_1, r_2) = [1, 3)$, the AoI is $t - g_1 = t - 0 = t$, while at time $t$ in interval $[r_2, r_3) = [3, 5)$, the AoI is $t - g_2 = t - 2$. At time $t \geq r_3 = 5$, the AoI is $t - g_3 = t - 4$.

AoI scheduling has two critical properties: i) all updates need not be processed, and ii) the AoI metric depends on the time-difference between the instants at which two consecutive updates are processed completely. Property i) makes the problem combinatorial, in the sense that an algorithm has to decide which subset of updates should be processed, while property ii) correlates the decisions across time. Together, they make AoI scheduling fundamentally different and challenging compared to the classical scheduling for minimizing flow time, completion time, makespan, etc.

Since the definition of AoI in \cite{Dai13, Kaul12}, a large body of work has been reported on scheduling for minimizing the AoI, however, the analysis is mostly restricted to stochastic inputs, as well as for some fixed scheduling algorithms. For example, for a single source-destination pair, \cite{Dai13, Kaul12, Gaurav14, Gaurav13, Gaurav11} considered queuing models such as $M/M/1$ (where updates arrive with exponentially distributed inter-arrival times and sizes\footnote{Size (or equivalently, transmission/processing/service time) of an update is equal to the total time required to completely transmit/process/serve the update.}) and at any time at most one update can be transmitted) and $D/G/1$ (where inter-arrival times of updates are deterministic, sizes may follow any general distribution, and at any time at most one update can be transmitted), and analyzed the AoI for fixed scheduling policies such as the first-come-first-serve (FCFS), last-come-first serve (LCFS), etc. For a multi-source $M/M/1$ queuing models, where updates arrive from multiple sources and at any time, at most one update (from one source) can be
transmitted to the destination. [25, 17] analyzed the distributional properties of the AoI for each source, with fixed scheduling policies such as FCFS, LCFS, etc.

In prior work, optimality results (with respect to AoI minimization) for causal policies are known only for simpler settings, such as when there is a single source that can generate updates at any time [24], or when inter-generation time distribution is exponential. For complicated models such as with multiple sources, the performance guarantees for causal policies have been established mostly in terms of their competitive ratio that is defined as the ratio of the cost of a causal policy, and an optimal offline policy that knows the entire update generation times and their sizes in advance. For example, in a discrete-time system with multiple sources, when the update inter-generation time and size distributions are geometric, [10] showed that a causal randomized policy has a constant competitive ratio. Recently, similar results were shown in [18, 20] for continuous-time systems where update inter-generation time and size distributions belong to a class of general distributions.

In a major departure from prior work on AoI, in this paper, we consider the AoI minimization problem for the arbitrary arrival model, where updates arrive at a source at arbitrary times and have arbitrary sizes. The goal is to find a causal policy that minimizes the AoI, where the possible decisions at any time are i) whether to preempt an ongoing update transmission on generation of a new update, and ii) if no update is under transmission, then choose which update to transmit among the available updates. Similar to prior work [11, 10, 18, 20, 19], we characterize the performance of any causal policy using the metric of competitive ratio.

For a single source-destination pair with arbitrary arrival model, the SRPT policy that is optimal for minimizing the flow-time, also intuitively appears to be a reasonable policy for minimizing the AoI. However, as we show in Example 3 (Section 2), for the considered problem, the competitive ratio of SRPT is arbitrarily large.

Another natural policy for AoI minimization is a greedy policy that at each time, chooses to transmit that update for which the ratio of the reduction in AoI upon its completion (if not preempted) and the remaining size at time, is maximum. In the arbitrary arrival model, one can construct update generation sequences such that this greedy policy repeatedly preempts the update under transmission without transmitting any update completely, for a long time. Recall that the AoI decreases only when an update is completely transmitted. Hence, establishing competitive ratio guarantees for the greedy policy is difficult.

Contributions

As described above, both the SRPT and the greedy policy on their own may not have good competitive ratio performance. However, for certain classes of inputs (update generation sequences), individually, both have complementarily appealing features. With this motivation, we propose a policy called $SRPT^+$, that at any point in time, either uses SRPT, or the greedy policy depending on the state of the system. In particular, when an update $i$ is under transmission, $SRPT^+$ preempts the update $i$ if (and only if) a new update $j$ is generated with size at most the remaining size of the update under transmission, and begins to transmit update $j$ (similar to SRPT). On the other hand, when no update is being transmitted, following the greedy policy, $SRPT^+$ begins to transmit the update for which the ratio of the reduction in AoI (upon its complete transmission) and the remaining size, is maximum.

The basic idea behind $SRPT^+$ is that the update that provides maximum reduction in AoI per unit transmission time (until completion) should be transmitted with priority. At the same time, preemption should not delay the completion time of updates. We show that for a single source destination pair with arbitrary arrival model, the competitive ratio for
SRPT$^+$ is at most 4. Essentially, we show that for each update $i$ generated at the source, the delay between its generation time and the earliest time when SRPT$^+$ completely transmits update $i$, or an update generated after it, is at most 4 times the corresponding quantity for an optimal offline policy $\pi^*$. Compared to prior work on AoI minimization, this is the first result that provides a constant competitive ratio upper bound for the arbitrary arrival model.

Subsequently, we propose a simpler policy than SRPT$^+$, called SRPT$^L$ that at any time when no update is being transmitted, begins to transmit the latest generated update, irrespective of its size or AoI reduction. Moreover, SRPT$^L$ preempts the update under transmission only if a new update is generated with smaller size (compared to the remaining size of the update under transmission). We show that the competitive ratio of SRPT$^L$ is at most 29.

## 2 System Model

We consider a source-destination pair, where updates are generated at the source at arbitrary time instants $g_1, g_2, \cdots$, with arbitrary sizes (transmission times required to completely transmit the updates) $s_1, s_2, \cdots$ (where $g_i, s_i \geq 0, \forall i$). At any time, the source may transmit at most one update to the destination, however, an update under transmission can be preempted at any time, to allow transmission of a different update.

Let $\Pi$ denote the set of all causal (online) scheduling policies (in short, policies) that at any time $t$, using only the available causal information, decides which update the source transmits at time $t$. For any policy $\pi \in \Pi$, the age of information (AoI) at time $t$ is $\Delta_\pi(t) = t - \lambda^\pi(t)$, where $\lambda^\pi(t)$ denotes the generation time of the latest update of the source that has been completely transmitted until time $t$, under policy $\pi$. Thus, the AoI decreases only when an update is completely transmitted under policy $\pi$. The (time) average AoI ($\overline{\text{AoI}}$) is defined as $\Delta_\pi = \lim_{t \to \infty} \int_0^t \Delta_\pi(\tau) d\tau / t$.

The objective is to find a causal policy $\pi \in \Pi$ that minimizes the $\overline{\text{AoI}}$. However, instead of directly finding the optimal causal policy, in this paper, we consider a particular causal policy called SRPT$^+ \in \Pi$, and show that its competitive ratio (Definition 2) is at most 4.

> **Definition 2.** Let $I = \{(g_1, s_1), (g_2, s_2), \cdots \}$ denote a particular sequence of updates that are generated at the source. Moreover, let $\pi^*$ denote an optimal offline policy (for minimizing $\overline{\text{AoI}}$) that knows $I$ ahead of time. For any causal policy $\pi \in \Pi$, its competitive ratio is $\text{CR}_\pi = \max_I \{\Delta_\pi(I)/\Delta_{\pi^*}(I)\}$.

To illustrate the challenges in minimizing the $\overline{\text{AoI}}$, we first show that the competitive ratio of the well-known SRPT policy is arbitrarily large. In the considered setting, with SRPT, at each time $t$, the update with the least remaining time (difference of $s_i$, and the total time for which update $i$ has been under transmission until time $t$) is transmitted.

> **Example 3.** Let $I_1 = \{(\epsilon/(m-i), 1/2) | i \in \{0, \cdots, m-1\}\}$, where $m$ is a positive integer, and $\epsilon > 0$. Also, let $I_2 = \{((1, 1)||i \in \mathbb{N}\}$. Consider the setting where the update generation sequence is $I = I_1 \cup I_2$, and the initial AoI is $\Delta(0) = 0$.

Note that for any update $i \in I_1$ and $j \in I_2$, the size $s_i < s_j$. Hence, before transmitting any update belonging to $I_2$, SRPT completely transmits all the updates in $I_1$. Moreover, the sum of the sizes of all the updates in $I_1$ is $m/2$. Thus, any update belonging to $I_2$ can begin to transmit under SRPT only at time $t \geq m/2$. Also, notice that the generation time of the last update in $I_1$ is $\epsilon$. Combining the above two facts, we get that under SRPT, at any time $t \leq m/2$, the AoI $\Delta_{\text{SRPT}}(t) \geq t - \epsilon$. Thus, choosing $m \to \infty$ and $\epsilon \to 0^+$, we get that under SRPT, the $\overline{\text{AoI}}$ is $\Delta_{\text{SRPT}}(I) \to \infty$. 

In contrast, consider a policy $\pi$, that at any time $t$ when no update is being transmitted, begins to transmit the latest generated update (if any), until completion (without preemption). Clearly, for the considered update generation sequence $I$, $\pi$ transmits each update in $I$, starting immediately after its generation. Thus, under policy $\pi$, with input $I$, the $\overline{\Delta I}$ is $\sum_2(I) = 3/2$, which implies that the $\overline{\Delta I}$ for an optimal offline policy $\pi^*$ is $\sum_2(I) \leq 3/2$ (i.e. finite). Hence, the competitive ratio of SRPT is $CR_{SRPT} = \max_I \{\sum_2(I)/\sum_2(I)\} \rightarrow \infty$.

**Notations**

We denote the generation time of the $i^{th}$ update (equivalently, update $i$) at the source by $g_i$ (thus, the relations $i < j$ and $g_i < g_j$ are equivalent). With respect to policy $\pi$, define $b^\pi_i$ as the earliest time instant when $\pi$ begins to transmit an update $j$ with generation time $g_j \geq g_i$ ($j$ may or may not be equal to $i$ because all updates need not be transmitted in order). Further, define $r^\pi_i \geq b^\pi_i$ as the earliest time instant when the transmission of an update $k$ with generation time $g_k \geq g_i$ completes under policy $\pi$ (update $k$ may or may not be same as update $i$, or the update $j$ whose transmission began at $b^\pi_i$, due to preemption). Note that the generation time of the latest completely transmitted update i.e. $\lambda^\pi(t) < g_i$, $\forall t < r^\pi_i$. As shown in Figure 2, if policy $\pi$ completely transmits update $i + 1$ without or before completely transmitting update $i$, then $r^\pi_i = r^\pi_{i+1}$.

Let $\delta_i = g_i - g_{i-1}$ denote the inter-generation time of successive updates $i - 1$ and $i$, which is independent of policy $\pi$. Define $\nu^\pi_i = r^\pi_i - g_i = (r^\pi_i - b^\pi_i) + (b^\pi_i - g_i) = d^\pi_i + w^\pi_i$, where $d^\pi_i = r^\pi_i - b^\pi_i$ and $w^\pi_i = b^\pi_i - g_i$. Note that $\nu^\pi_i$, $w^\pi_i$ and $d^\pi_i$ are update-based metrics that are defined for each generated update. Figure 2 shows a sample AoI plot for policy $\pi \in \Pi$, along with the quantities defined above.

Next, we derive a general expression for the $\overline{\Delta I}$ of any causal or offline policy $\pi$, in terms of the quantities defined so far.

### 3 General Expression for Average AoI

**Lemma 4.** For any policy $\pi$ (causal or offline), the $\overline{\Delta I}$ is

$$
\overline{\Delta I} = \lim_{t \to \infty} \frac{1}{I} \sum_{i=1}^{R(t)} \left[ \frac{\delta_i^2}{2} + \delta_i \nu^\pi_i \right] = \lim_{t \to \infty} \frac{1}{I} \left[ \sum_{i=1}^{R(t)} \frac{\delta_i^2}{2} + \sum_{i=1}^{R(t)} \delta_i w^\pi_i + \sum_{i=1}^{R(t)} \delta_i d^\pi_i \right],
$$

(1)

where $R(t)$ denotes the number of updates generated until time $t$.

**Proof.** See Appendix A. □

Notably, Lemma 4 expresses the $\overline{\Delta I}$ for any policy $\pi$ (causal or offline) in terms of $\delta_i$’s that are independent of policy $\pi$, and update-based metrics $\nu^\pi_i$’s (i.e. $w^\pi_i$’s and $d^\pi_i$’s). Also, from (1), we get that the $\overline{\Delta I}$ for an optimal offline policy $\pi^*$ (that knows the update generation sequence in advance) is

$$
\overline{\Delta I^*} = \lim_{t \to \infty} \frac{1}{I} \sum_{i=1}^{R(t)} \left[ \frac{\delta_i^2}{2} + \delta_i \nu^\pi_i \right],
$$

(2)

where $\nu^\pi_i = v^\pi_i - g_i$, and $v^\pi_i$ is the earliest time instant when $\pi^*$ completes the transmission of an update $j \geq i$. Lemma 5 shows that $\nu^\pi_i \geq \min_{j \geq i} \{g_j + s_j\} - g_i$, for each update $i$. 
6 Minimizing Age of Information under Arbitrary Arrival Model with Arbitrary Packet Size

\[ \Delta(t) \]

\[ g_1, g_2, g_3, r_1^\pi, r_2^\pi, r_3^\pi \text{ time (t)} \]

\[ \Delta(t) \]

\[ \pi(t) \]

\[ \nu_i^\pi = r_i^\pi - g_i \geq \nu_i^{\pi \text{min}} \]

where \( \nu_i^{\pi \text{min}} = \min_{j \geq i} \{ g_j + s_j \} - g_i \geq 0 \).

\[ \text{Proof.} \quad \text{Note that the earliest time instant by which an update } i \text{ generated at time } g_i \text{ can be completely transmitted is } g_i + s_i, \text{ where } s_i = s_i(g_i) \text{ is the size of update } i \text{ at generation. Therefore, the earliest time instant when an update } j \geq i \text{ can be completely transmitted is } \min_{j \geq i} \{ g_j + s_j \}. \text{ Hence, for any causal or offline policy } \pi, \text{ we have } r_i^\pi \geq \min_{j \geq i} \{ g_j + s_j \}, \text{ which implies that } \nu_i^\pi = r_i^\pi - g_i \geq \min_{j \geq i} \{ g_j + s_j \} - g_i = \nu_i^{\pi \text{min}}. \]

In the next section, we propose a novel policy called SRPT\(^+\) that has features of both a greedy policy and SRPT, and show that the AoI\(^+\) for SRPT\(^+\) is at most 4 times the AoI\(^+\) for an optimal offline policy \( \pi^* \).

4 SRPT\(^+\) Policy

At time \( t \), let \( s_i(t) \) denote the remaining size of update \( i \), and \( \lambda(t) \) be the generation time of the latest update completely transmitted until time \( t \). If the remaining size \( s_i(t) \) of update \( i \) is transmitted from time \( t \) onwards (and not preempted ever), then its transmission completes at time \( t + s_i(t) \), causing an instantaneous reduction in AoI of \( \max \{ g_i - \lambda(t), 0 \} \) units at time instant \( t + s_i(t) \). Thus, for each update \( i \) available at time \( t \), i.e., \( s_i(t) > 0 \), we define an index

\[ \gamma_i(t) = \frac{\max \{ g_i - \lambda(t), 0 \}}{s_i(t)}, \]

which represents the ratio of the benefit obtained by transmitting update \( i \), and the cost (time required to transmit it). Let \( \Gamma(t) = \{ i | \gamma_i(t) > 0, s_i(t) > 0 \} \) denote the set of all updates available at time \( t \) such that \( \gamma_i(t) > 0 \).

Using the index \( \gamma_i(t) \), we propose a policy called SRPT\(^+\) (Algorithm\(^+\)) that at any time \( t \), makes one of the following two decisions. i) If no update is under transmission, then it begins to transmit the update \( i' \) such that \( \gamma_i' = \arg \max_{j \in \Gamma(t)} \gamma_j(t) \) (and idles if the set \( \Gamma(t) \) is empty), and ii) if an update \( i \) is under transmission, then update \( i \) is preempted by update \( j \) if and only if a new update \( j \) is generated with size \( s_j = s_j(t) \leq s_i(t) \).

\[ \gamma_i(t) = \frac{\max \{ g_i - \lambda(t), 0 \}}{s_i(t)} < \frac{\max \{ g_j - \lambda(t), 0 \}}{s_j(t)} = \gamma_j(t). \]

Thus, under SRPT\(^+\), when an update \( j \) preempts an update \( i \) at time \( t \), this implicitly means that \( \gamma_j(t) > \gamma_i(t) \) and \( j \in \Gamma(t) \). This shows that SRPT\(^+\) is essentially a greedy policy with...
Algorithm 1 SRPT+ Policy.

1: At any time $t$,
2: if an update $i$ is under transmission then
3: if a new update $j$ is generated with size $s_j = s_j(t) \leq s_i(t)$ then
4: preempt update $i$ and begin to transmit update $j$.
5: else
6: continue transmitting update $i$.
7: end if
8: else if the set $\Gamma(t)$ is non-empty then
9: begin to transmit update $j = \arg\max_{i \in \Gamma(t)} \gamma_i(t)$ (ties broken arbitrarily).
10: else
11: idle until a new update is generated.
12: end if

respect to index $i$, except that to preempt an update $i$ at time $t$ (with remaining size $s_i(t)$), it additionally requires that the size $s_j(t)$ of update $j$ (that is to preempt update $i$) is no more than $s_i(t)$. Hence, at the time instant $t$ when the transmission of an update $i$ begins, its index $\gamma_i(t)$ is maximum among all the updates. Also, preemption does not increase the earliest time after time $t$, when an update from $\Gamma(t)$ gets completely transmitted.

Remark 7. SRPT+ transmits an update $i$ at time $t$, only if it belongs to $\Gamma(t)$, i.e., $\gamma_i(t) > 0$. In fact, at time $t$, if update $i$ does not belong to $\Gamma(t)$ ($\gamma_i(t) = 0$), then SRPT+ never transmits it in the future as well. This is because $\lambda(t)$ is a non-decreasing function of $t$, and the generation time $g_i$ is fixed for update $i$. Thus, at any time $t$, if $\gamma_i(t) = 0$ (i.e., $\max\{g_i - \lambda(t), 0\} = 0$), then $\gamma_i(t') = 0$, $\forall t' \geq t$.

We next illustrate SRPT+ (Algorithm 1) using a pertinent example that brings out its critical properties.

Example 8. Let the AoI at time $t = 0$ be $\Delta(0) = 0$, which implies $\lambda(0) = 0$. Consider an update generation sequence $\mathcal{I} = \{(g_i, s_i)\}$, where the set of updates generated in time interval $[0, 2]$ are $\{(0, 1.45), (0.25, 1.25), (0.75, 1), (1, 0.5), (1.25, 0.3), (1.8, 0.1)\}$. Let the updates be numbered (ordered) in increasing order of their generation time.

Clearly, at time $t = 0$, the only available update is update 1, i.e., $(0, 1)$, and no update is under transmission. Moreover, the index $i$ for the update available at time $t = 0$ is $\gamma_1(0) = \max\{g_1 - \lambda(0), 0\}/s_1(0) = 0$, which implies that the update does not lie in $\Gamma(0)$. Hence, SRPT+ discards update 1, and no transmission happens until time $t = 0.25$, when update 2 is generated.

Until time $t = 0.25$, since no update is transmitted by SRPT+, at time $t = 0.25$, $\lambda(0.25) = 0$ (and AoI $\Delta(t = 0.25) = t - \lambda(t) = 0.25$). Thus, $\gamma_2(0.25) = \max\{g_2 - \lambda(0.25), 0\}/s_2(0.25) = (0.25 - 0)/1.25 = 0.2 > 0$. Thus, SRPT+ begins to transmit update 2 at time $t = 0.25$, which remains under transmission at time $t = 0.75$ with remaining size $s_2(0.75) = 1.25 - (0.75 - 0.25) = 0.75$, and index $\gamma_2(0.75) \approx 0.33$, when update 3 is generated. Until time $t = 0.75$, since no update has been completely transmitted by SRPT+, $\lambda(0.75) = 0$. For update 3 the size at time $t = 0.75$ is $s_3(0.75) = s_3 = 1$, and index $\gamma_3(0.75) = \max\{g_3 - \lambda(0.75), 0\}/s_3(0.75) = (0.75 - 0)/1 = 0.75$. Clearly, $\gamma_2(0.75) < \gamma_3(0.75)$, but since update 2 is already under transmission and $s_2(0.75) = 0.75 < s_3(0.75) = 1$, SRPT+ continues to transmit update 2.

At time $t = 1$, update 2 is still under transmission with remaining size $s_2(1) = 1.25 - (1 - 0.25) = 0.5$, and index $\gamma_2(1) = \max\{g_2 - \lambda(1), 0\}/s_2(1) = (0.25 - 0)/0.5 = 0.5$. However,
update 4 is generated at time $t = 1$, with size $s_4 = 0.5 \leq s_2(1)$. Hence, SRPT$^+$ preempts update 2, and begins to transmit update 4 (at time $t = 1$).

Subsequently, at time $t = 1.25$, update 4 is under transmission with remaining size $s_4(1.25) = (0.5 - (1.25 - 1)) = 0.25$ which is less than the size of update 5 generated at time $t = 1.25$. Hence, SRPT$^+$ continues to transmit update 4 until time $t = 1.5$, when its transmission completes. Thus, at time $t = 1.5$, the latest completely transmitted update is update 4, which implies $\lambda(1.5) = g_4 = 1$.

Since, $\lambda(1.5) = g_4 = 1$, at time $t = 1.5$, the index $\gamma_i(1.5) = \max\{g_i, 1.0\}/s_i(1.5) = 0$, for each update $i$ generated until time $t = 1$. Thus, the only update with a positive index at time $t = 1.5$ (i.e., the only update in $\Gamma(1.5)$) is update 5 (i.e. $(1.25, 0.3)$) with index $\gamma_5(1.5) = \max\{g_5 - \lambda(1.5, 0)/s_5(1.5) = (1.25 - 1)/0.3 \approx 0.83$. Hence, SRPT$^+$ begins to transmit update 5 starting at time $t = 1.5$, which completes at time $t = 1.8$. Thus, at time $t = 1.8$, $\lambda(1.8) = g_5 = 1.25$, and AoI is $t - \lambda(t) = 1.8 - 1.25 = 0.55$.

Subsequently, at time $t = 1.8$, update 6 is generated, and has index $\gamma_6(1.8) = 0.55 > 0$. Since no other update $i$ has a positive index $\gamma_i(1.8)$ (at time $t = 1.8$), SRPT$^+$ begins to transmit update 6 at time $t = 1.8$, and completes it at time $t = 1.9$. Thus, at time $t = 1.9$, $\lambda(1.9) = g_6 = 1.8$, and AoI is $t - \lambda(t) = 1.9 - 1.8 = 0.1$. Following time $t = 1.9$, no update is available with positive index $[3]$. Hence, SRPT$^+$ idles thereafter.

Note that for the given update generation sequence in interval $[0, 2]$, under SRPT$^+$, only three updates are completely transmitted: i) update 4 i.e. $(1, 0.5)$, completely transmitted at time $t = 1.5$, ii) update 5 i.e. $(1.25, 0.3)$, completely transmitted at time $t = 1.8$, and iii) update 6 i.e. $(1.8, 0.1)$, completely transmitted at time $t = 1.9$. Thus, under SRPT$^+$, AoI increases linearly from 0 at time $t = 0$ to 1.5 at time $t = 1.5$. Then, as soon as the transmission of update 4 completes, AoI decreases to $1.5 - \lambda(1.5) = 1.5 - g_4 = 1.5 - 1 = 0.5$. Then, AoI increases linearly to 0.8 at time $t = 1.8$, when AoI decreases to $1.8 - \lambda(1.8) = 1.8 - g_5 = 0.55$. Subsequently, AoI increases linearly to 0.65 at time $t = 1.9$, then decreases to 0.1 when update 6 is completely transmitted, and increases linearly thereafter. On simple computation, we find that $\overline{\text{AoI}}$ for SRPT$^+$ in interval $[0, 2]$ is 1.395 time units.

Using brute force technique, we find that for the given update generation sequence in interval $[0, 2]$, with an optimal offline policy $\pi^*$, only updates 5 and 6 are completely transmitted. In particular, $\pi^*$ completely transmits update 5 over the time interval $(1.25, 1.55]$, and update 6 over the time interval $(1.8, 1.9]$, incurring $\overline{\text{AoI}}$ equal to 1.3825 time units.

The main result of this section is as follows.

**Theorem 9.** The competitive ratio of SRPT$^+$ (Algorithm [2]) is $\text{CR}_{\text{SRPT}^+} \leq 4$.

The main technical Lemma to prove Theorem 9 are as follows.

**Lemma 10.** Let superscripts $+$ and $\ast$ respectively denote SRPT$^+$, and an optimal offline policy $\pi^*$.

1. For any update $i$, $w_i^+ \leq 2\nu_i^\ast$, where $w_i^+ = b_i^+ - g_i$, while $\nu_i^\ast = r_i^\ast - g_i$.
2. $\sum_{i=1}^{R(t)} \delta_i d_i^+ \leq 2 \sum_{i=1}^{R(t)} \delta_i \nu_i^\ast$, where $\delta_i = g_i - g_{i-1}$, while $d_i^+ = r_i^+ - b_i^+$.

**Proof.** See Appendix [3]
Proof of Theorem 9. From (1) and Lemma 10, we get that the AoI for SRPT+ is

$$
\Delta_{SRPT^+} \leq \lim_{t \to \infty} \frac{1}{t} \left[ \sum_{i=1}^{R(t)} \frac{\delta_i^2}{2} + \sum_{i=1}^{R(t)} \delta_i (2\nu_i^*) + 2 \sum_{i=1}^{R(t)} \delta_i \nu_i^* \right],
$$

$$
= \lim_{t \to \infty} \frac{1}{t} \left[ \sum_{i=1}^{R(t)} \frac{\delta_i^2}{2} + 4 \sum_{i=1}^{R(t)} \delta_i \nu_i^* \right],
$$

\(\leq\) \(\lim_{t \to \infty} \frac{4}{t} \left[ \sum_{i=1}^{R(t)} \frac{\delta_i^2}{2} + \sum_{i=1}^{R(t)} \delta_i \nu_i^* \right],
$$

\((a)\) \(\leq\) \(\lim_{t \to \infty} \frac{4}{t} \left[ \sum_{i=1}^{R(t)} \frac{\delta_i^2}{2} + \sum_{i=1}^{R(t)} \delta_i \nu_i^* \right],
$$

\((b)\) \(\equiv\) \(4 \cdot \Delta_{x^*},
$$

where in (a) since \(\delta_i^2 \geq 0\), we upper bound it by \(4\delta_i^2\), and (b) follows from (2).

**Remark 11.** Note that \(\delta_i\)'s are inter-generation time of updates that only depends on when the updates are generated, while \(\nu_i^*\) additionally depends on the sizes of updates (Lemma 5). Since the generation time of updates and their sizes can be arbitrary (independent of each other), in (a) of (4), \(\delta_i \nu_i^*\)'s can be arbitrary large compared to \(\delta_i^2\)'s. ▶

Next, we analyze a simpler policy than SRPT+, called SRPT\(^L\), and show that its competitive ratio is at most 29.

5 **SRPT\(^L\) Policy**

Following any time instant \(t\) (when the generation time of the latest completely transmitted update is \(\lambda(t)\)), if an update \(i\) that is generated at time \(g_i > \lambda(t)\) is completely transmitted, the reduction in AoI is \(g_i - \lambda(t)\). Clearly if \(g_i\) is large (i.e. update \(i\) is the latest generated update), the reduction in AoI is also large. Motivated by this fact, we consider a causal policy called SRPT\(^L\) (Algorithm 2), defined as follows: At any time \(t\), if no update is under transmission, SRPT\(^L\) begins to transmit the latest generated update \(i^* = \arg \max_i g_i\) (if \(i^*\) is yet to be transmitted completely, else wait until next update is generated). Else, if an update \(i\) is under transmission at time \(t\), then SRPT\(^L\) preempts update \(i\) and begins to transmit update \(j\) (at time \(t\)), only if update \(j\) is generated at time \(t\) with size \(s_j \leq s_i(t)\).

**Algorithm 2** SRPT\(^L\) Policy.

1: At any time \(t\),
2: if an update \(i\) is under transmission then
3: if a new update \(j\) is generated with size \(s_j(t) \leq s_i(t)\) then
4: preempt update \(i\) and begin to transmit update \(j\).
5: else
6: continue transmitting update \(i\).
7: end if
8: else if latest generated update is yet to be transmitted completely then
9: begin to transmit the latest generated update.
10: else
11: idle until a new update is generated.
12: end if
Regarding SRPT$^L$, the fact that only a smaller update $j$ (compared to the remaining size of the update $i$ under transmission) can preempt update $i$, ensures that when SRPT$^L$ begins to transmit an update, the earliest time when an update $j \geq i$ is completely transmitted (i.e. $r^L_{ij}$), is never delayed due to preemption. In Lemma 12, we show some critical properties of SRPT$^L$.

▶ Lemma 12. Let superscripts $L$ and $\pi^*$ respectively denote SRPT$^L$ and $\pi^*$.
1. For any update $i$, $w^L_i \leq \nu^\min_i \leq \nu^*_i$, where $w^L_i = b^L_i - g_i$, while $\nu^\min_i$ and $\nu^*_i$ are as defined in Lemma 5.
2. At the time instant $t$ when SRPT$^L$ begins to transmit an update $i$, its generation time $g_i$ is the latest among all updates generated until time $t$. That is, SRPT$^L$ either never begins to transmit an update $i$, or begins to transmit it at some time $t \in [g_i, g_{i+1})$.
3. If SRPT$^L$ begins to transmit an update $i$ (at time $b^L_i$), then $r^L_{ij} = \min\{b^L_i + s_i, \min_{j \geq i+1}\{g_j + s_j\}\}$. Additionally, for such an update $i$, $d^L_i = r^L_{ij} - b^L_i \leq \nu^\min_i \leq \nu^*_i$.

Proof. See Appendix C.

▶ Remark 13. At any time $t$, while choosing the latest generated update $i^*$ for transmission, SRPT$^L$ neither considers the update size $s_{i^*}(t)$, nor the AoI at time $t$.

In Appendix D, we illustrate the properties of SRPT$^L$ using the update generation sequence $I$ considered in Example 3. Next, we show the main result of this section.

▶ Theorem 14. The competitive ratio of SRPT$^L$ (Algorithm 2) is $\text{CR}_{SRPT^L} \leq 29$.

Proof. See Appendix E.

6 Conclusions

In this paper, we have considered a scheduling problem for a single source-destination pair. The goal is to find a causal scheduling policy that minimizes the average age of information (AoI). Unlike most prior works that assume update generation sequence to be either deterministic or stochastic, we have considered an arbitrary arrival model, where updates of arbitrary sizes arrive at the source at arbitrary time instants, and at any time, the possible decisions are whether to preempt the update under transmission on arrival of a new update, and if no update is under transmission, then which update (among the available updates) to transmit. We have proposed two causal scheduling policies called SRPT$^+$ and SRPT$^L$, and upper bounded their competitive ratio by comparing against an optimal offline policy. In particular, we have shown that SRPT$^+$ and SRPT$^L$ have constant competitive ratios, at most 4 and 29, respectively. The remaining open question is: whether similar (constant) competitive ratio guarantees can be shown for causal policies in systems with multiple sources.

References

A  Proof of Lemma 4

Proof. By definition, \( \overline{\Delta}_{\pi} = \lim_{t \to \infty} \int_{0}^{t} \Delta_{\pi}(\tau) d\tau / t. \) The main idea for showing (1) is to express the integral \( \lim_{t \to \infty} \int_{0}^{t} \Delta_{\pi}(\tau) d\tau \) for a policy \( \pi \) (causal or offline) in terms of \( \delta_i \)'s and \( \nu_i \)'s. As shown in Figure 2, for a fixed policy \( \pi \), the area under its AoI plot (which is equal to the integral \( \lim_{t \to \infty} \int_{0}^{t} \Delta_{\pi}(\tau) d\tau \)) can be partitioned into segments of area \( \delta_i^2 / 2 + \delta_i \nu_i \), corresponding to each update \( i \). Thus, summing the area of the segments across all updates, we get \( \lim_{t \to \infty} \int_{0}^{t} \Delta_{\pi}(\tau) d\tau = \sum_{i=1}^{R(t)} (\delta_i^2 / 2 + \delta_i \nu_i) \), where \( R(t) \) denotes the number of updates generated at the source until time \( t \).

\[
\overline{\Delta}_{\pi} = \lim_{t \to \infty} \frac{1}{t} \int_{0}^{t} \Delta_{\pi}(\tau) d\tau = \lim_{t \to \infty} \frac{1}{t} \sum_{i=1}^{R(t)} \left[ \frac{\delta_i^2}{2} + \delta_i \nu_i \right],
\]

\[
= \lim_{t \to \infty} \frac{1}{t} \sum_{i=1}^{R(t)} \left[ \frac{\delta_i^2}{2} + \delta_i (w_i^+ + d_i^+) \right],
\]

\[
= \lim_{t \to \infty} \frac{1}{t} \left[ \sum_{i=1}^{R(t)} \frac{\delta_i^2}{2} + \sum_{i=1}^{R(t)} \delta_i w_i^+ + \sum_{i=1}^{R(t)} \delta_i d_i^+ \right].
\]

B  Proof of Lemma 10

Before discussing the detailed proof of Lemma 10 in Subsections B.1 and B.2, we provide its proof sketch.

Proof Sketch. (1) \( \nu_i^* = r_i^* - g_i \) implies that \( r_i^* = g_i + \nu_i^* \). Thus, there exists an update \( j^* \geq i \) that the optimal offline policy \( \pi^* \) completes transmitting at time \( r_i^* = g_i + \nu_i^* \). To prove the first result, we consider the following cases. i) No update is under transmission at time \( g_i \). Then the transmission of update \( i \) starts immediately at generation, which implies \( w_i^+ = 0 \leq \nu_i^* \). ii) An update \( f \) is under transmission at time \( g_i \). We consider the following two sub-cases.

a) Under SRPT\(^+\), update \( f \) is preempted by some update \( j \geq i \). We show that if update \( f \) is preempted by some update \( j \geq i \), then it must happen until time \( g_j \) (generation time of update \( j \) that \( \pi^* \) completely transmits until time \( r_j^* = g_j + \nu_j^* = r_j^* \)). Since \( g_j \leq r_j^* \), \( g_j = g_j + \nu_j^* \) (by definition), we get that \( b_i^+ = g_i + \nu_i^* \). Thus \( w_i^+ = b_i^+ - g_i \leq \nu_i^* \).

b) Under SRPT\(^+\), update \( f \) is not preempted, i.e., its transmission completes (at time \( r_j^* \)). Since update \( f \) is not preempted, its size \( s_f(g_i) = s_f(g_i) - (g_i - g_i) < s_j \), \( \forall j \geq i \). Thus, \( s_f(g_i) < \min_{j \geq i} \{g_j + s_j\} = g_i = \nu_i^{\text{min}} \leq \nu_i^* \) (Lemma 5), which implies that the completion
time of transmission of update $f$ (under SRPT$^+$) is $r_f^+ \leq g_i + \nu_i^*$. Following this, to show that $w_i^* \leq 2\nu_i^*$ (i.e., $b_i^+ \leq g_i + 2\nu_i^*$), we show that in interval $(r_f^+, g_i + 2\nu_i^*)$ (which is of length greater than $\nu_i^*$), SRPT$^+$ cannot be transmitting updates generated prior to update $i$ all the time (and must begin to transmit an update $j \geq i$ at time $b_i^+ \leq 2\nu_i^*$). In particular, we show that the sum of the size of updates $k < i$ with index $\gamma_k(t) \geq \gamma_i(t)$ (at any time $t \in (r_f^+, g_i + 2\nu_i^*)$ cannot be greater than $\nu_i^*$. This is because the size of $j^*$ is at most $\nu_i^*$, and the reduction in AoI on directly transmitting $j^* \geq i$ (after $r_f^+$) is greater than that possible if all updates $k < i$ are completely transmitted.

(2) For the second result, we partition the set of updates generated at the source into subsets $A_1, A_2, \ldots$, such that $b_i^+ = b_i^+$, (i.e., under SRPT$^+$, the earliest time instant when the transmission of an update $j \geq i$ begins is equal to the earliest time instant when the transmission of an update $j' \geq i'$ begins), if and only if $i, j \in A_n$ for some $n$. Then, we show that for each $n$, $\sum_{i \in A_n} \delta_i d_i^+ \leq 2 \sum_{i \in A_n} \delta_i \nu_i^*$. The intuition for this result is captured in Figure 3.

\begin{figure}[h]
\centering
\includegraphics[width=0.5\textwidth]{figure3.png}
\caption{Slope of the dashed line represents the index $[\gamma]$ for update $m$ (latest generated update in $A_n$) at time $b_m^+$, which is largest among all updates in $A_n$. Note that $\sum_{i \in A_n} \delta_i d_i^+$ is at most equal to the area of the rectangular region (total shaded region), which is at most twice the area of the darker shaded region, a lower bound on $\sum_{i \in A_n} \delta_i \nu_i^*$.}
\end{figure}

\section*{B.1 For each update $i$, $w_i^+ \leq 2\nu_i^*$, where $w_i^+ = b_i^+ - g_i$, while $\nu_i^* = r_i^* - g_i$.}

\begin{proof}
If no update is under transmission at time $g_i$ (the generation time of update $i$), then SRPT$^+$ begins to transmit update $i$ immediately after generation. Thus, $b_i^+ = g_i$, which implies $w_i^+ = b_i^+ - g_i = 0 \leq 2\nu_i^*$ (since $\nu_i^* \geq 0$). Therefore, to show that $w_i^+ \leq 2\nu_i^*$, it is sufficient to consider the case where SRPT$^+$ is transmitting some update $f$ at time $g_i$, when update $i$ gets generated.

Recall that SRPT$^+$ preempts the update $f$ under transmission whenever an update $j$ is generated with size $s_j \leq s_f(g_j)$. Therefore, under SRPT$^+$, either update $f$ is completely transmitted at time $g_i + s_f(g_i)$, or it gets preempted, and some update $j \geq i$ begins transmission at time $g_j$. Thus, the earliest time instant when SRPT$^+$ completes the transmission of update $f$ (which is under transmission at time $g_i$), or an update $j$ (generated at $g_j \geq g_i$) is $r_f^+ = \min\{g_i + s_f(g_i), \min_{j \geq i}\{g_j + s_j\}\} \leq \min_{j \geq i}\{g_j + s_j\} \leq r_f^+$, where the last inequality follows from Lemma 5. Since $\nu_i^* = r_i^* - g_i$, we get that $r_f^+ \leq r_i^* = g_i + \nu_i^*$. Now, consider the following two complementary cases.

\[ \lambda^+(b_m^+) \]

\[ \sum_{i \in A_n} \delta_i d_i^+ \leq 2 \sum_{i \in A_n} \delta_i \nu_i^* \]
B.1.1 Update $f$ is preempted, and an update $j \geq i$ is completely transmitted at time $r^+_f \leq r^+_i = g_i + \nu^*_i$.

By definition, $w^+_i = b^+_i - g_i \leq r^+_i - g_i$. Also, at $r^+_f$, an update $j \geq i$ is completely transmitted. Therefore, $r^+_i = r^+_f$. Combining these two facts, we get $w^+_i \leq r^+_f - g_i \leq r^+_i - g_i = \nu^*_i \leq 2\nu^*_i$.

B.1.2 Update $f$ is not preempted, i.e. the transmission of update $f$ itself completes at time $r^+_f \leq r^+_i = g_i + \nu^*_i$.

Let $w^+_i > 2\nu^*_i$, i.e., until time $g_i + 2\nu^*_i$, under SRPT+, only the updates generated strictly before $g_i$ are under transmission. With SRPT+, an update $j$ with generation time $g_j < g_f$ can never be under transmission at time $t \geq r^+_f$ (because for such an update $j$, the index $\gamma_j(t) = 0$). Thus, the assumption that $w^+_i > 2\nu^*_i$ implies that in interval $(r^+_f, g_i + 2\nu^*_i]$, SRPT+ begins to transmit only those updates that got generated in interval $(g_f, g_i)$ are under transmission.

Note that in interval $(r^+_f, g_i + 2\nu^*_i]$, update $i$ is available at the source, and by definition, SRPT+ never idles when a new update (compared to the completely transmitted updates) is available. Thus, the fact that SRPT+ does not begin transmitting update $j \geq i$ in interval $(r^+_f, g_i + 2\nu^*_i]$, implies that at each time instant $t \in (r^+_f, g_i + 2\nu^*_i]$, SRPT+ is transmitting some update generated in interval $(g_f, g_i)$. However, as we show next in Proposition 15 this cannot be true, contradicting the assumption that $w^+_i > 2\nu^*_i$. Thus, we conclude that $w^+_i \leq 2\nu^*_i$ in this case as well.

Proposition 15. Under SRPT+, there exists some time instant $t \in (r^+_f, g_i + 2\nu^*_i]$, when none of the updates generated in interval $(g_f, g_i)$ is under transmission.

Proof. We prove the result using contradiction. With SRPT+, let at each time instant $t \in (r^+_f, g_i + 2\nu^*_i]$, some update $k$ that is generated in interval $(g_f, g_i)$ is under transmission. Consider the time instant $r^*_i = g_i + \nu^*_i$. Since $r^+_f \leq g_i + \nu^*_i$, we get that $r^*_i \in (r^+_f, g_i + 2\nu^*_i]$. By definition of $r^*_i$, there exists some update $j^* \geq i$ that $\pi^*$ transmits completely by time $r^*_i = g_i + \nu^*_i$. Thus, for update $j^*$, $g_{j^*} + s_{j^*} \leq g_i + \nu^*_i$. Since $g_{j^*} \geq g_i$, this implies that $s_{j^*} \leq \nu^*_i$. Also, because $s_{j^*} \geq 0$, we have $g_{j^*} \leq g_i + \nu^*_i$. Thus, at time $g_i + \nu^*_i$, the size $s_{j^*}(g_i + \nu^*_i) = s_{j^*}(g_{j^*}) = s_{j^*} \leq \nu^*_i$, where (a) follows because the remaining size of an update can never increase. Using this fact, as well as the fact that $j^* \geq i$ (i.e. $g_{j^*} \geq g_i$), we get the following lower bound on the index $[3]$ for update $j^*$ at time $g_i + \nu^*_i$:

$$
\gamma_{j^*}(g_i + \nu^*_i) = \frac{(a) \quad g_{j^*} - \lambda^+(g_i + \nu^*_i)}{s_{j^*}(g_i + \nu^*_i)} \geq \frac{g_i - \lambda^+(g_i + \nu^*_i)}{\nu^*_i},
$$

(5)

where in (a), $\lambda^+(g_i + \nu^*_i)$ denotes the generation time of the latest update that is completely transmitted by SRPT+ until time $g_i + \nu^*_i$.

Let $K$ denote the set of all updates generated in interval $(g_f, g_i)$ that SRPT+ transmits completely/partially in interval $(g_i + \nu^*_i, g_i + 2\nu^*_i]$ (because $r^*_i = g_i + \nu^*_i \in (r^+_f, g_i + 2\nu^*_i]$), the interval $(g_i + \nu^*_i, g_i + 2\nu^*_i] \subseteq [r^+_f, g_i + 2\nu^*_i])$. At each time instant $t \in (g_i + \nu^*_i, g_i + 2\nu^*_i]$, since SRPT+ is transmitting updates from subset $K$ despite having update $j^*$ with greater generation time (compared to the updates in $K$), it follows that the index $[3]$ of the updates in $K$ that SRPT+ transmits, must be greater than $[5]$. Also, the sum of the sizes of updates in $K$ must be at least $\nu^*_i$ (as the length of interval $(g_i + \nu^*_i, g_i + 2\nu^*_i]$ is $\nu^*_i$). Therefore, if all the updates in $K$ are completely transmitted, then it must lead to reduction in AoI at least as much as $g_i - \lambda^+(g_i + \nu^*_i)$. However, this cannot be true because the generation time of
the updates in \( \mathcal{K} \) is strictly less than \( g_i \). Thus, SRPT\(^+\) cannot be transmitting updates from subset \( \mathcal{K} \) at each time instant \( t \in (g_i + \nu^*_i, g_i + 2\nu^*_i] \subseteq (r_f, g_i + 2\nu^*_i] \). That is, there exists some time instant \( t \in (r_f, g_i + 2\nu^*_i] \) when none of the updates generated in interval \((g_f, g_i)\) is under transmission (with SRPT\(^+\)).

B.2 \[ \sum_{i=1}^{R(t)} \delta_id_i^+ \leq 2 \sum_{i=1}^{R(t)} \delta_i\nu_i^+, \text{ where } \delta_i = g_i - g_{i-1}, \text{ while } d_i^+ = r_i^+ - b_i^+. \]

**Proof.** Recall that \( b_i^+ \) is the earliest time instant when the transmission of an update \( j \geq i \) begins under SRPT\(^+\). By definition, \( b_i^+ \)'s may be equal (common) for successively generated updates. Let the set of updates generated at the source until time \( t \) (where \( t \to \infty \)) be partitioned into the largest subsets \( A_1, A_2, A_3, \ldots \), such that for all updates \( i \) within a subset \( A_n \), \( b_i^+ \)'s are equal. To prove \( \sum_{i=1}^{R(t)} \delta_id_i^+ \leq 2 \sum_{i=1}^{R(t)} \delta_i\nu_i^+ \), we show that for any subset \( A_n \),

\[ \sum_{i \in A_n} \delta_id_i^+ \leq 2 \sum_{i \in A_n} \delta_i\nu_i^+. \tag{6} \]

Consider a subset \( A_n \) (for some \( n \)). Let the updates in \( A_n \) be numbered as \( 1_n, 2_n, \ldots, m_n \), in increasing order of their generation time. By definition of \( A_n \), \( b_i^+ \)'s are equal (say, \( k_n \)). Therefore, \( \forall i \in A_n \), the earliest time instant when the transmission of an update \( j \geq i \) begins under SRPT\(^+\) begins to transmit update \( m_n \) (latest generated update in the subset \( A_n \)), as shown next.

**Proposition 16.** At time \( b_{m_n}^+ \), SRPT\(^+\) begins to transmit update \( m_n \).

**Proof.** By definition, \( b_i^+ \) is the earliest time instant when the transmission of an update \( j \geq i \) begins. Since \( b_{m_n}^+ = b_{2n}^+ = \cdots = b_{m_n}^+ \), at time \( b_{m_n}^+ \), either the transmission of update \( m_n \), or an update generated after \( m_n \) (say, \( k_n > m_n \)), begins. But if the transmission of \( k_n \) begins before update \( m_n \), then by definition, \( b_k^+ = b_{m_n}^+ \), i.e. \( k_n \in A_n \), which is not true (by definition of \( A_n \)). This implies that at time \( b_{m_n}^+ \), SRPT\(^+\) begins to transmit update \( m_n \). ▶

By definition, once SRPT\(^+\) begins to transmit update \( m_n \) at time \( b_{m_n}^+ \), it never transmits any update \( j \) generated before \( m_n \), at time \( t > b_{m_n}^+ \) (i.e. after SRPT\(^+\) begins to transmit update \( m_n \)). Therefore, \( \forall i \in A_n \), the earliest time instant when the transmission of an update \( j \geq i \) completes is \( r_i^+ = r_{m_n}^+ \) (the update whose transmission completes at time \( r_{m_n}^+ \) need not be update \( m_n \)). Therefore, \( d_i^+ = r_i^+ - b_i^+ = r_{m_n}^+ - b_{m_n}^+ = d_{m_n}^+ \), \( \forall i \in A_n \). Hence,

\[ \sum_{i \in A_n} \delta_id_i^+ = d_{m_n}^+ \cdot \sum_{i \in A_n} \delta_i. \tag{7} \]

As discussed in Remark 8, regardless of whether SRPT\(^+\) begins to transmit an update due to larger index \( \nu \) (when no update is being transmitted) or due to preemption by smaller sized update compared to the remaining size of the update under transmission, the time instant when SRPT\(^+\) begins to transmit an update, the update’s index \( \nu \) is the largest. Therefore, at time \( b_{m_n}^+ \), when SRPT\(^+\) begins to transmit update \( m_n \), the index \( \gamma_{m_n}(b_{m_n}^+) \) must be the maximum among all the available updates. Thus, \( \forall j \in A_n = \{1_n, \ldots, m_n \} \),

\[ \frac{g_{m_n} - \lambda^+(b_{m_n}^+)}{s_{m_n}} \geq \frac{g_j - \lambda^+(b_{m_n}^+)}{s_j}, \tag{8} \]

where \( s_j = s_j(b_{m_n}^+) = s_j(g_j) \) is the remaining size of update \( j \in A_n \) at time \( b_{m_n}^+ \) under SRPT\(^+\), while the superscript \( + \) in \( \lambda^+(\cdot) \) denotes SRPT\(^+\).

Without loss of generality, let update \( 0_n \) be the latest update generated before \( g_n \) (generation time of update \( 1_n \in A_n \)). Then \( \delta_{1_n} = g_{1_n} - g_{0_n} \), where \( g_{0_n} \) denotes the
Minimizing Age of Information under Arbitrary Arrival Model with Arbitrary Packet Size

generation time of update $0_n$. Recall that $\lambda^+(b_{m_n}^+)$ is equal to the generation time of latest update that has been completely transmitted by SRPT$^+$ until time $b_{m_n}^+$. Since update $m_n$ is the only update in $A_n$, whose transmission begins until time $b_{m_n}^+$, it follows that $\lambda^+(b_{m_n}^+) \leq 0_n$. Therefore, $0_n - \lambda^+(b_{m_n}^+) = \epsilon \geq 0$.

Note that $g_j - \lambda^+(b_{m_n}^+) = \epsilon + \sum_{i=1}^j \delta_i, \forall j \in \{1, \ldots, m_n\}$. Thus, (8) can be written as

$$\frac{\epsilon + \sum_{i=1}^{m_n} \delta_i}{s_{m_n}} \geq \frac{\epsilon + \sum_{j=1}^j \delta_j}{s_j},$$

which implies that $\forall j \in A_n,$

$$s_j \geq s_{m_n} \cdot \left(\frac{\epsilon + \sum_{i=1}^{m_n} \delta_i}{\epsilon + \sum_{j=1}^j \delta_j}\right),$$

Now, we connect the decisions of $\pi^*$ (an optimal offline policy) with those of SRPT$^+$, over each subset $A_n$.

**Proposition 17.** For all updates $j \in A_n = \{1, \ldots, m_n\},$

$$\nu_j^* \geq d_{m_n}^+ \cdot \left(\frac{\sum_{i=1}^{m_n} \delta_i}{\sum_{j=1}^j \delta_j}\right).$$

**Proof.** Let $\theta_j = \sum_{i=1}^j \delta_i / \sum_{i=1}^{m_n} \delta_i, \forall j \in A_n = \{1, \ldots, m_n\}$ (by definition, $\theta_j \leq 1$). From Lemma 5, we know that for any update $j$, $r_j^* \geq \min_{i \geq j} \{g_i + s_i\}$, which implies

$$r_j^* \geq \min_{i \in \{j, \ldots, m_n\}} \{g_i + s_i\}, \min_{i > m_n} \{g_i + s_i\},$$

$$\geq \min_{i \in \{j, \ldots, m_n\}} \{g_i + s_{m_n} \cdot \theta_j\}, \min_{i > m_n} \{g_i + s_i\},$$

where we get (a) because for any update $i \in A_n, s_i \geq s_{m_n} \cdot \theta_i$ (from (10)).

Since $r_j^* = r_j^* - g_j \geq r_j^* - b_j^* = d_j^*$, on subtracting $g_j$ from both sides of (12) and denoting $\phi_{ij} = g_i - g_j \forall i \geq j,$

$$\nu_j^* \geq \min_{i \in \{j, \ldots, m_n\}} \{\phi_{ij} + s_{m_n} \cdot \theta_j\}, \min_{i > m_n} \{\phi_{ij} + s_i\},$$

where we get (a) because $\phi_{ij} = g_i - g_j \geq 0, \forall i \geq j$.

Note that under SRPT$^+$, if transmission of update $m_n$ (which starts at time $b_{m_n}^+$) completes, then $r_{m_n}^+ = b_{m_n}^+ + s_{m_n}$. Else, if update $m_n$ gets preempted, then $r_{m_n}^+ = \min_{i > m_n} \{g_i + s_i\}$. Combining these two facts, we get $r_{m_n}^+ = \min \{b_{m_n}^+ + s_{m_n}, \min_{i > m_n} \{g_i + s_i\}\}$. Thus, $d_{m_n}^+ = r_{m_n}^+ - b_{m_n}^+ = \min \{s_{m_n}, \min_{i > m_n} \{g_i + s_i\}\}. \forall j \in A_n, \text{we have} g_i - b_{m_n}^+ \leq g_j - g_j = \phi_{ij}$. Therefore, $d_{m_n}^+ \leq \min \{s_{m_n}, \min_{i > m_n} \{\phi_{ij} + s_i\}\}$. Multiplying both sides by $\theta_j$, we get $d_{m_n}^+ \cdot \theta_j \leq \min \{s_{m_n} \cdot \theta_j, \min_{i > m_n} \{\phi_{ij} + s_i\} \cdot \theta_j\}$. Since $\theta_j \leq 1$ (by definition), we get

$$d_{m_n}^+ \cdot \theta_j \leq \min \{s_{m_n} \cdot \theta_j, \min_{i > m_n} \{\phi_{ij} + s_i\}\}.$$

Comparing (13) and (14), we get (11).
Proof. Consider the following two complementary cases.

C.2 At the time instant \( t \) when SRPT\(^L\) begins to transmit an update \( i \), its generation time \( g_i \) is the latest among all updates generated until time \( t \). That is, SRPT\(^L\) either never begins to transmit an update \( i \), or begins to transmit it at some time \( t \in [g_i, g_{i+1}) \).

Proof. Recall that SRPT\(^L\) begins to transmit an update \( i \) either a) by preempting another update at time \( g_i \), or b) at the earliest time instant \( t \) when update \( i \) is the latest generated update and no update is under transmission (which implies that \( t \in [g_i, g_{i+1}) \)). Hence, if SRPT\(^L\) begins to transmit an update \( i \) at time \( t \), then \( t \in [g_i, g_{i+1}) \).
C.3 If SRPT\(^L\) begins to transmit an update \(i\) (at time \(b^L_i\)), then
\[ r^L_i = \min\{b^L_i + s_i, \min_j\geq i+1\{g_j + s_j\}\}. \]
Additionally, for such an update \(i\), \(d^L_i = r^L_i - b^L_i \leq \nu^\text{min}_i \leq \nu^*_i\).

Proof. Note that SRPT\(^L\) preempts the update under transmission whenever a new update is generated with size at most the remaining size of the update under transmission. Therefore, if SRPT\(^L\) begins to transmit an update \(i\) at time \(b^L_i \in [g_i, g_{i+1})\), then the earliest time instant when the transmission of an update \(j \geq i\) completes is \(r^L_i = \min\{b^L_i + s_i, \min_j\geq i+1\{g_j + s_j\}\}\). Further, by definition, \(d^L_i = r^L_i - b^L_i = \min\{s_i, \min_j\geq i+1\{(g_j - b^L_j) + s_j\}\} \leq \min\{s_i, \min_j\geq i+1\{(g_j - g_i) + s_j\}\} = \min_j\geq i+1\{g_j + s_j\} - g_i \leq \nu^\text{min}_i \leq \nu^*_i\), where (a) follows because \(b^L_i \geq g_i\), and (b) follows from the definition of \(\nu^\text{min}_i\).

D An example to illustrate the properties of SRPT\(^L\)

Example 18. At time \(t = 0\), let the AoI \(\Delta(0) = 0\). In time interval \([0, 2]\), the update generation sequence \(\mathcal{I} = \{(0, 1.45), (0.25, 1.25), (0.75, 1), (1, 0.5), (1.25, 0.3), (1.8, 0.1)\}\), and the updates \(i\) (i.e. \((g_i, s_i)\)) in \(\mathcal{I}\) are numbered (ordered) in increasing order of their generation time \(g_i\).

At time \(t = 0\), since no update is under transmission, SRPT\(^L\) begins to transmit the latest update, i.e. update 1. Subsequently, at time \(t = 0.25\), update 2 is generated with size \(s_2 = 1.25 > (1.45 - 0.25) = s_1(0.25)\). Therefore, update 1 remains under transmission. At time \(t = 0.75\), update 3 is generated with size \(s_3 = 0.75 > (1.45 - 0.75) = s_1(0.75)\), and hence update 3 does not preempt update 1 (i.e. update 1 remains under transmission). Similarly, at time \(t = 1\) and \(t = 1.25\) respectively, updates 4 and 5 are generated, and none of them preempt update 1 because at time \(t = 1\) and \(t = 1.25\), the remaining size of update 1 is smaller than the sizes of updates 4 and 5 respectively. Thus, the transmission of update 1 completes at time \(t = 1.45\).

At time \(t = 1.45\), no update is under transmission, and the latest update i.e. update 5 is available for transmission. Therefore, SRPT\(^L\) begins to transmit update 5 at time \(t = 1.45\), and transmits it completely by time \(t = 1.45 + s_5 = 1.45 + 0.3 = 1.75\). At time \(t = 1.75\), since latest update is completely transmitted, SRPT\(^L\) idles until time \(t = 1.8\) when update 6 is generated. In time interval \([1.8, 1.9]\), SRPT\(^L\) transmits update 6 completely. Thereafter, in absence of a new update, SRPT\(^L\) idles until time \(t = 2\).

In summary, in interval \([0, 2]\), SRPT\(^L\) completely transmits update 1 (i.e. \((0, 1.45)\)) over interval \([0, 1.45]\), update 5 (i.e. \((1.25, 0.3)\)) over interval \((1.45, 1.75)\) and update 6 (i.e. \((1.8, 0.1)\)) over interval \((1.8, 1.9)\). Thus, the AoI increases linearly from 0 at time \(t = 0\) to 1.45 at time \(t = 1.45\). At time \(t = 1.45\), the generation time of latest completely transmitted update is \(\lambda(1.45) = g_1 = 0\), which implies that the AoI \(\Delta(1.45) = 1.45 - \lambda(1.45) = 1.45\). Thus, there is no reduction in AoI because of complete transmission of update 1. Consequently, the AoI increases linearly from 1.45 at time \(t = 1.45\) to 1.75 at time \(t = 1.75\), and then instantaneously decreases to 1.75 - \(g_5 = 1.75 - 1.25 = 0.5\) after update 5 is completely transmitted. Then, AoI increases linearly from 0.5 at time \(t = 1.75\) to 0.65 at time \(t = 1.9\), and then decreases instantaneously to 1.9 - \(g_6 = 1.9 - 1.8 = 0.1\) after update 6 is completely transmitted. Thereafter, AoI again starts to increase linearly.

Thus, we get that the average AoI (i.e. \(\overline{\text{AoI}}\)) for SRPT\(^L\) in interval \([0, 2]\) is 1.6325 time units. Recall from Example 3 that for the same update generation sequence \(\mathcal{I}\), the \(\overline{\text{AoI}}\) for SRPT\(^*\) is 1.395 time units, whereas the \(\overline{\text{AoI}}\) for an optimal offline policy \(\pi^*\) is 1.3825 time units.
Proof. By definition, \( b_i^L \geq g_i \) is the earliest time instant when SRPT\(^L\) begins to transmit an update \( j \geq i \). We partition the set of all updates generated at the source into sets \( G^L_- \) and \( G^L_\geq \), based on \( b_i^L \)'s. In particular, we define \( G^L_\geq \) as the subset of all updates \( i \) such that \( b_i^L = g_i \) (i.e., under SRPT\(^L\), the transmission of update \( i \) begins immediately at its generation time), and \( G^L_- \) is the subset of all updates \( i \) such that \( b_i^L > g_i \). Then, the AoI [1] for SRPT\(^L\) can be written as

\[
\overline{\Delta}_{\text{SRPT}^L} = \lim_{t \to \infty} \frac{1}{t} \left[ \sum_{i=1}^{R(t)} \frac{\delta_i^2}{2} + \sum_{i=1}^{R(t)} \delta_i w_i^L + \sum_{i=1}^{R(t)} \delta_i d_i^L \right],
\]

\[
= \lim_{t \to \infty} \frac{1}{t} \left[ \sum_{i=1}^{R(t)} \frac{\delta_i^2}{2} + \left( \sum_{i \in G^L_-} \delta_i w_i^L + \sum_{i \in G^L_\geq} \delta_i w_i^L \right) + \left( \sum_{i \in G^L_-} \delta_i d_i^L + \sum_{i \in G^L_\geq} \delta_i d_i^L \right) \right],
\]

\[
(\approx) \lim_{t \to \infty} \frac{1}{t} \left[ \sum_{i=1}^{R(t)} \frac{\delta_i^2}{2} + \sum_{i \in G^L_-} \delta_i w_i^L + \sum_{i \in G^L_-} \delta_i d_i^L \right] + \left( \sum_{i \in G^L_\geq} \delta_i d_i^L \right), \tag{18}
\]

where we get (a) because by definition of \( G^L_- \), for any \( i \in G^L_- \), \( b_i^L = g_i \), which implies \( w_i^L = b_i^L - g_i = 0 \).

From property 1 in Lemma 12, we get that for each \( i \in G^L_- \), \( w_i^L \leq \nu_i^* \), which implies

\[
\sum_{i \in G^L_-} \delta_i w_i^L \leq \sum_{i \in G^L_-} \delta_i \nu_i^*. \tag{19}
\]

Further, by definition, of \( G^L_- \), SRPT\(^L\) begins to transmit each update in \( G^L_- \) at generation time. Therefore, from property 3 of Lemma 12 we get that for each update \( i \in G^L_- \), \( d_i^L \leq \nu_i^* \), which implies

\[
\sum_{i \in G^L_-} \delta_i d_i^L \leq \sum_{i \in G^L_-} \delta_i \nu_i^*. \tag{20}
\]

Substituting (19) and (20) in (18), we get

\[
\overline{\Delta}_{\text{SRPT}^L} \leq \lim_{t \to \infty} \frac{1}{t} \left[ \sum_{i=1}^{R(t)} \frac{\delta_i^2}{2} + \sum_{i \in G^L_-} \delta_i \nu_i^* + \sum_{i \in G^L_-} \delta_i \nu_i^* \right] + \lim_{t \to \infty} \frac{1}{t} \sum_{i \in G^L_-} \delta_i d_i^L,
\]

\[
= \lim_{t \to \infty} \frac{1}{t} \left[ \sum_{i=1}^{R(t)} \frac{\delta_i^2}{2} + \sum_{i \in G^L_-} \delta_i \nu_i^* \right] + \lim_{t \to \infty} \frac{1}{t} \sum_{i \in G^L_-} \delta_i d_i^L,
\]

\[
\leq \lim_{t \to \infty} \frac{1}{t} \left[ \sum_{i=1}^{R(t)} \frac{\delta_i^2}{2} + \sum_{i=1}^{R(t)} \delta_i \nu_i^* \right] + 28 \overline{\Delta}_{\nu^*},
\]

\[
\overset{(b)}{=} 29 \overline{\Delta}_{\nu^*}, \tag{21}
\]

where (a) follows from Lemma 19 (discussed below), and (b) follows from (2).

\begin{lemma}
\[
\lim_{t \to \infty} \frac{1}{t} \sum_{i \in G^L_-} \delta_i d_i^L \leq 28 \overline{\Delta}_{\nu^*} = \lim_{t \to \infty} \frac{28}{t} \int_0^t \Delta_{\nu^*}(\tau) d\tau.
\]
\end{lemma}
Proof Sketch (for detailed proof, see Appendix F). The basic idea is to partition the set $G^T_\leq$ into subsets $A_n$’s such that corresponding to each subset $A_n$, there exists a time-interval $\chi_n$, such that

$$\sum_{i \in A_n} \delta_i d_i^t \leq c_n \cdot \int_{\chi_n} \Delta_{SRP^T}(\tau) d\tau,$$

(22)

for some constant $c_n$. We consider $A_n$’s, such that the generation time $b_i^t$ for all updates $i \in A_n$ (for fixed $n$) are equal. Correspondingly, we define $\chi_n$ as the interval between the generation time of the latest update generated before the updates in $A_n$, and the generation time of the earliest update whose transmission begins under LCFS after all the updates in $A_n$ are generated.

Since $A_n$’s partition $G^T_\leq$, summing both sides of (22) over all $n$, we get

$$\lim_{t \to \infty} \frac{1}{t} \sum_{i \in G^T_\leq} \delta_i d_i^t \leq \lim_{t \to \infty} \frac{1}{t} \sum_{n} \int_{\chi_n} c_n \Delta_{\pi^*}(\tau) d\tau.$$

(23)

Note that the L.H.S. of (23) is equal to the L.H.S. of Lemma 19. Thus, to prove Lemma 19, we show that the R.H.S. of Lemma 19 is an upper bound on the R.H.S. of (23). To show this, we classify the intervals $\chi_n$’s into disjoint groups such that $c_n$’s are equal for each interval $\chi_n$ within a group. For the choice of $A_n$’s in our proof, we identify two groups i.e. $G^T_\leq(1)$ and $G^T_\leq(2)$, such that $c_n = 8$ for each $n \in G^T_\leq(1)$, and $c_n = 10$ for each $n \in G^T_\leq(2)$.

Thus, (23) simplifies to

$$\lim_{t \to \infty} \frac{1}{t} \sum_{n \in G^T_\leq(1)} \int_{\chi_n} \Delta_{\pi^*}(\tau) d\tau \leq \frac{8}{t} \int_{0}^{t} \Delta_{\pi^*}(\tau) d\tau = 8\Delta_{\pi^*},$$

(24)

Further, we show that $\forall n \in G^T_\leq(1)$, $\chi_n$’s are disjoint, and $\cup_{n \in G^T_\leq(1)} \chi_n \subseteq [0, t]$. Therefore,

$$\lim_{t \to \infty} \frac{8}{t} \int_{0}^{t} \Delta_{\pi^*}(\tau) d\tau = \lim_{t \to \infty} \frac{8}{t} \int_{0}^{t} \Delta_{\pi^*}(\tau) d\tau = 8\Delta_{\pi^*},$$

(25)

However, $\chi_n$’s for $n \in G^T_\leq(1)$ may not be disjoint, but we show that alternate intervals are disjoint, i.e. intervals $\chi_1, \chi_3, \chi_5, \cdots$ are mutually disjoint, and intervals $\chi_2, \chi_4, \chi_6, \cdots$ are mutually disjoint. Hence, $\lim_{t \to \infty} \frac{10}{t} \sum_{n \in G^T_\leq(2)} \int_{\chi_n} \Delta_{\pi^*}(\tau) d\tau$

$$= \lim_{t \to \infty} \frac{10}{t} \sum_{n \in G^T_\leq(2), n \text{ even}} \int_{\chi_n} \Delta_{\pi^*}(\tau) d\tau + \lim_{t \to \infty} \frac{10}{t} \sum_{n \in G^T_\leq(2), n \text{ odd}} \int_{\chi_n} \Delta_{\pi^*}(\tau) d\tau,$$

$$\leq \lim_{t \to \infty} \frac{10}{t} \int_{0}^{t} \Delta_{\pi^*}(\tau) d\tau + \lim_{t \to \infty} \frac{10}{t} \int_{0}^{t} \Delta_{\pi^*}(\tau) d\tau,$$

$$= 10\Delta_{\pi^*} + 10\Delta_{\pi^*}.$$

(26)

Substituting (25) and (26) into (24), we get Lemma 19.

Proof of Lemma 19

Proof. Partition the set $G^T_\leq$ into largest subsets $A_1, A_2, \cdots$, such that a) for any subset $A_n$, $b_i^t$ is same for all updates $i \in A_n$, and b) for update $i \in A_n$ and $j \in A_{n'}$, $b_i^t < b_j^t$, whenever $n < n'$. Further, let $B$ denote the set of all subsets $A_n$’s that partition $G^T_\leq$ ($A_n$’s are sets of updates, while $B$ is a set of subsets $A_n$’s).
Then, we can write
\[
\lim_{t \to \infty} \frac{1}{t} \sum_{i \in G^L_t} \delta_i d_i^L = \lim_{t \to \infty} \frac{1}{t} \sum_{A_n \in \mathcal{B} \cap \mathcal{A}_n} \sum_{i \in A_n} \delta_i d_i^L.
\]
(27)

Consider a subset \(A_n \in \mathcal{B}\) (for some \(n\)). Without loss of generality, let the updates in \(A_n\) be numbered (ordered) as \(1_n, 2_n, \ldots, m_n\), in increasing order of their generation times. Also, let the latest update generated before update \(1_n\) be \(0_n\). Note that \(0_n \notin A_n\).

By definition of \(A_n\), \(b_{1_n}^L = \cdots = b_{m_n}^L\). Additionally, since SRPT always transmits a new update after it begins to transmit a new update, we have
\[
r_{1_n}^L = \cdots = r_{m_n}^L.
\]
(28)

Combining these two facts, we get
\[
\sum_{i \in A_n} \delta_i d_i^L = \left( \sum_{i \in A_n} \delta_i \right) d_{m_n}^L = (g_{m_n} - g_{0_n}) d_{m_n}^L.
\]
(29)

Let \(k_n \geq m_n\) denote the update that SRPT begins to transmit at time \(b_{m_n}^L\). Then \(d_{m_n}^L = d_{k_n}^L\). Using Lemma 12, we get \(d_{m_n}^L = d_{k_n}^L \leq \nu_{k_n}^{\min}\). Thus, upper-bounding \(d_{k_n}^L\) in (29) by \(\nu_{k_n}^{\min}\), we get
\[
\sum_{i \in A_n} \delta_i d_i^L \leq \left( \sum_{i \in A_n} \delta_i \right) \nu_{k_n}^{\min} = (g_{m_n} - g_{0_n}) \nu_{k_n}^{\min}.
\]
(30)

Remark 22. Note that \(b_{k_n}^L = b_{m_n}^L\) (by definition of \(k_n\)). Therefore, if \(k_n \in G^L_{G^L_{k_n}}\), then it must be that \(k_n = m_n\) (follows from the definition of \(A_n\)'s, and the fact that \(k_n \geq m_n\)). Otherwise (i.e. if \(k_n \notin G^L_{G^L_{k_n}}\), \(k_n\) must be the earliest generated update after \(m_n\), else, the updates \(m_n + 1, \ldots, k_n - 1\) would also lie in \(A_n\), which is not possible (by definition of \(m_n\)).

Next, we partition \(\mathcal{B}\) (the set of subsets \(A_n\)'s) as follows:
\[
G^L_1(1) = \{ A_n \in \mathcal{B} | g_{m_n} - g_{0_n} \geq \nu_{k_n}^{\min} \}, \quad \text{and} \quad G^L_2(2) = \{ A_n \in \mathcal{B} | g_{m_n} - g_{0_n} < \nu_{k_n}^{\min} \}.
\]
(31)

Then, we can write
\[
\lim_{t \to \infty} \frac{1}{t} \sum_{A_n \in \mathcal{B} \cap \mathcal{A}_n} \delta_i d_i^L = \lim_{t \to \infty} \frac{1}{t} \sum_{A_n \in G^L_1(1) \cap \mathcal{A}_n} \sum_{i \in A_n} \delta_i d_i^L + \lim_{t \to \infty} \frac{1}{t} \sum_{A_n \in G^L_2(2) \cap \mathcal{A}_n} \sum_{i \in A_n} \delta_i d_i^L.
\]
(32)

where (a) follows from (30).

Proposition 23. \(i\) \(\lim_{t \to \infty} \frac{1}{t} \sum_{A_n \in G^L_1(1)} (g_{m_n} - g_{0_n}) \nu_{k_n}^{\min} \leq 8\Delta_{\pi^*}\), \(ii\) \(\lim_{t \to \infty} \frac{1}{t} \sum_{A_n \in G^L_2(2)} (g_{m_n} - g_{0_n}) \nu_{k_n}^{\min} \leq 20\Delta_{\pi^*}\).

Proof. See Appendix C.

Combining (27), (32) and Proposition 23, we get \(\lim_{t \to \infty} \frac{1}{t} \sum_{i \in G^L_t} \delta_i d_i^L \leq 28\Delta_{\pi^*}\).
Minimizing Age of Information under Arbitrary Arrival Model with Arbitrary Packet Size

G Proof of Proposition 23

G.1 \( \lim_{t \to \infty} \frac{1}{t} \sum_{A_n \in G^G_{\pi}(1)} (g_{m_n} - g_{0_n}) \nu_{k_n}^{\min} \leq 8 \bar{\Delta} \).

Proof. Consider the following general result.

\[ \text{i) SRPT}^L \text{ begins to transmit update } 0_n, \text{ and ii) } g_{m_n} - g_{0_n} \leq 2r_{0_n}^{\min}. \]

Proof. Since the subsets \( A_1, A_2, \cdots \) partition \( G^G_{\pi} \), an update may not lie in \( A_n \) either if it does not lie in \( G^G_{\pi} \) (i.e. the update lies in \( G_{n'}^G \)), or it lies in subset \( A_n' \) for some \( n' \neq n \). Because update \( 0_n \notin A_n \) and it is the latest generated update before the updates in \( A_n \) (by definition), either \( 0_n \in A_{n-1} \), which implies \( b_{0_n}^L < b_{1_n}^L \), or \( 0_n \in G_n^L \), which implies \( b_{0_n}^L = g_{0_n} < g_{1_n} \leq b_{1_n}^L \). Thus, in both cases \( b_{0_n}^L < b_{1_n}^L \), which implies \( b_{0_n}^L = \cdots = b_{m_n}^L \).

Recall that \( b_{0_n}^L \) and \( b_{1_n}^L \) are respectively the earliest time instants when under SRPT\(^L \), the transmission of an update \( j \geq 0_n \) and \( j' \geq 1_n \) begins. Since updates \( 0_n \) and \( 1_n \) are consecutively generated, and \( b_{0_n}^L < b_{1_n}^L \), we get that at \( b_{0_n}^L \), SRPT\(^L \) begins to transmit update \( 0_n \). Moreover, since SRPT\(^L \) begins to transmit update \( 0_n \), we get

\[ \nu_{0_n}^L = t_{0_n}^L - g_{0_n} = w_{0_n}^L + d_{0_n}^{(a)} \leq 2r_{0_n}^{\min} \leq 2r_{0_n}^*, \quad (33) \]

where \( (a) \) and \( (b) \) follows Lemma 12.

Note that whenever transmission of an update completes and there is a new update to transmit, SRPT\(^L \) begins to transmit it immediately. Therefore, if the earliest time when the transmission of an update \( j \geq 0_n \) completes is \( r_{0_n}^L < g_{m_n} \), then the transmission of some update \( j' \in \{1_n, \cdots, m_n - 1\} \) will begin before time \( g_{m_n} \). But this cannot be true because \( b_{1_n}^L = \cdots = b_{m_n}^L \). Hence, \( r_{0_n}^L \geq g_{m_n} \), which implies that \( r_{0_n}^L - g_{0_n} \geq g_{m_n} - g_{0_n} \). Comparing this result with (33), we get \( g_{m_n} - g_{0_n} \leq r_{0_n}^L - g_{0_n} \leq 2r_{0_n}^{\min} \).

From Proposition 24 and Remark 22 it follows that \( 0_n \) and \( k_n \geq m_n \) are two successive updates that SRPT\(^L \) begins to transmit. Therefore, the intervals \( \{g_{0_n}, g_{m_n}\}, \forall A_n \in B \) are subsets of the time intervals between the generation time of two successive updates that SRPT\(^L \) begins to transmit. Hence, the intervals \( \{g_{0_n}, g_{m_n}\}, \forall A_n \in B \) are disjoint, which implies

\[ \bar{\Delta} = \lim_{t \to \infty} \frac{1}{t} \int_0^t \Delta_{\pi'}(\tau) d\tau \geq \lim_{t \to \infty} \frac{1}{t} \sum_{A_n \in G^G_{\pi}(1)} \int_{g_{0_n}}^{g_{m_n}} \Delta_{\pi'}(\tau) d\tau \]

\[ \geq \lim_{t \to \infty} \frac{1}{t} \sum_{A_n \in G^G_{\pi}(1)} \int_{g_{0_n}}^{g_{m_n}} \Delta_{\pi'}(\tau) d\tau \]

\[ \tag{34} \]

where \( (a) \) follows because \( G^G_{\pi}(1) \) is a subset of \( B \) (from (31)), and summands in (34) are non-negative (by definition).

From Lemma 3 we know that the earliest time instant by which an offline optimal policy \( \pi^* \) can completely transmit an update \( j \geq 0_n \) is at least \( g_{0_n} + \nu_{0_n}^{\min} \). Thus, with \( \pi^* \), at any time \( t \in (g_{0_n}, g_{0_n} + \nu_{0_n}^{\min}) \), the generation time of the latest completely transmitted update is \( \lambda^*(t) \leq g_{0_n} \), which implies that the AoI of \( \pi^* \) at time \( t \in (g_{0_n}, g_{0_n} + \nu_{0_n}^{\min}) \) is \( \Delta_{\pi^*}(t) = t - \lambda^*(t) \geq t - g_{0_n} \). Hence,
\[
\int_{g_{0_n}}^{g_{m_n}} \Delta_x(\tau) d\tau \geq \int_{g_{0_n}}^{\min\{g_{m_n}, g_{0_n} + \nu_{0_n}^{\min}\}} \Delta_x(\tau) d\tau,
\]
\[
\geq \frac{\min\{(g_{m_n} - g_{0_n})^2, (\nu_{0_n}^{\min})^2\}}{2},
\]
\[
\geq \frac{(g_{m_n} - g_{0_n})^2}{8},
\]
\[
\geq \frac{(g_{m_n} - g_{0_n})\nu_{k_n}^{\min}}{8},
\]
(35)

where (a) follows from Proposition 24, and (b) is true for \(A_n \in G^L_\ell(1)\) (from (31)).

Comparing (34) and (35), we get
\[
\lim_{t \to \infty} \frac{1}{t} \sum_{A_n \in G^L_\ell(1)} (g_{m_n} - g_{0_n})\nu_{k_n}^{\min} \leq \lim_{t \to \infty} \frac{8}{t} \int_0^t \Delta_x(\tau) d\tau = 8\Sigma_x. \quad \blacksquare
\]

### G.2 \lim_{t \to \infty} \frac{1}{t} \sum_{A_n \in G^L_\ell(2)} (g_{m_n} - g_{0_n})\nu_{k_n}^{\min} \leq 20\Sigma_x.

**Proof.** From (25), we know that for each update \(i \in A_n\), \(r^L_i\)'s are equal. Therefore, we define
\[
r^L_{A_n} = r^L_{A_n} = r^L_{A_n} = \cdots = r^L_{m_n}.
\]
(36)

Note that \(r^L_i\)'s may also be equal for updates in successive subsets \(A_n\) and \(A_{n+1}\), for example, when update \(k_n\) is preempted by update \(k_{n+1}\). Therefore, we partition \(G^L_\ell(2)\) (31) into sets \(B_1, B_2, \cdots\) such that \(r^L_{A_n} = r^L_{A_{n+1}}\) if and only if both \(A_n\) and \(A_{n+1}\) lie in the same set \(B_\ell\) (for some \(\ell\)). Further, we define \(r^L_{B_\ell} = r^L_{A_n}, \forall A_n \in B_\ell\), and let the order \(B_1, B_2, \cdots\) be such that \(r^L_{B_1} < r^L_{B_2} < \cdots\). Then,
\[
\lim_{t \to \infty} \frac{1}{t} \sum_{A_n \in G^L_\ell(2)} (g_{m_n} - g_{0_n})\nu_{k_n}^{min} = \lim_{t \to \infty} \frac{1}{t} \sum_{\forall \ell} \sum_{A_n \in B_\ell} (g_{m_n} - g_{0_n})\nu_{k_n}^{min}.
\]
(37)

Consider any particular set \(B_\ell\). For notational clarity, we distinguish the subsets \(A_n \in B_\ell\) (and related variables such as \(g_{0_n}, g_{k_n}, \text{etc.}\)) by a superscript \(\ell\). Let the number of subsets \(A_n \in B_\ell\) be \(u_\ell\). Then, \(A^\ell_1, A^\ell_2, \cdots, A^\ell_{u_\ell}\) denotes the subsets \(A_n \in B_\ell\), in increasing order of \(g^\ell_{k_n}\)'s, where \(g^\ell_{k_n}\) denotes the generation time of update \(k^\ell_n\), and \(k^\ell_n\) is the earliest generated update that SRPT\(^L\) begins to transmit after all the updates in \(A^\ell_n\) are generated.

**Proposition 25.** i) \(\sum_{A^\ell_n \in B_\ell} (g_{m_n} - g_{0_n})\nu_{k_n}^{min,\ell} \leq 10 \int_{g_{k_1}}^{g_{k_1} + \nu_{k_1}^{min,\ell}} \Delta_x(\tau) d\tau, \) and ii) time intervals \(g_{k_1}^{\ell+2} + \nu_{k_1}^{min,\ell+2}\) are disjoint, \(\forall \ell\).

**Proof.** See Appendix H
With newly defined notations, we have
\[
\lim_{t \to \infty} \frac{1}{t} \sum_{\forall \ell} \sum_{A_\ell^t \in B_t} (g_{m_n}^\ell - g_{0_n}^\ell) \nu_{k_n}^{m,\ell} + \lim_{t \to \infty} \frac{1}{t} \sum_{\forall \ell} \sum_{A_\ell^t \in B_t} (g_{m_n}^\ell - g_{0_n}^\ell) \nu_{k_n}^{m,\ell}.
\]

\[
\leq \lim_{t \to \infty} \frac{1}{t} \sum_{\forall \ell} \sum_{1,3,5, \cdots} 10 \int g_{k_1}^{\ell} \Delta_x^*(\tau) d\tau + \lim_{t \to \infty} \frac{1}{t} \sum_{\forall \ell} \int g_{k_1}^{\ell} \Delta_x^*(\tau) d\tau,
\]

\[
= 20 \sum_{\pi^*},
\]

where we get (a) using the inequality in Proposition 25 and (b) follows because as shown in Proposition 25 \((g_{k_1}^\ell, g_{k_1}^{\ell+1}, \nu_{k_1}^{\ell})\) and \((g_{k_1}^{\ell+2}, g_{k_1}^{\ell+3}, \nu_{k_1}^{\ell+2})\) are disjoint sub-intervals of \((0, t]\), and the integrand \(\Delta_x^*(\tau) \geq 0, \forall \tau \geq 0\). From (37) and (38), we get
\[
\lim_{t \to \infty} \frac{1}{t} \sum_{A_n \in G_x^\ell(2)} (g_{m_n} - g_{0_n}) \nu_{k_n}^{m,\ell} \leq 20 \sum_{\pi^*}.
\]

H Proof of Proposition 25

H.1 \(\sum_{A_\ell^t \in B_t} (g_{m_n}^\ell - g_{0_n}^\ell) \nu_{k_n}^{m,\ell} \leq 10 \int g_{k_1}^{\ell} \Delta_x^*(\tau) d\tau.\)

Proof. For set \(B_t = \{A_1^t, A_2^t, \cdots, A_{u_t}^t\}\), consider the sequence of updates

\[
0_1^t, k_1^t, 0_2^t, k_2^t, 0_3^t, k_3^t, \cdots, 0_{u_t}^t, k_{u_t}^t.
\]

By definition, \(0_i^t\) is generated before the earliest generated update in \(A_i^t\), while as discussed in Remark 22, \(k_i^t\) is either the latest generated update in \(A_n^t\) (i.e. update \(m_i^t\)), or the earliest generated update after \(m_i^t\). Therefore, \(0_i^t\) and \(k_i^t\) always refers to distinct updates, and

\[
g_{m_n}^\ell - g_{0_n}^\ell \leq g_{k_n}^\ell - g_{0_n}^\ell.
\]

Further, since the updates in \(A_n^t\) are generated before the updates in \(A_n^{t+1}\) (follows from the numbering/ordering of \(A_n^t\’s\)), we get \(0_1^t < k_1^t \leq 0_2^t < k_2^t \leq 0_3^t < k_3^t \leq \cdots \leq 0_{u_t}^t < k_{u_t}^t\). Thus,

\[
\sum_{A_\ell^t \in B_t} (g_{m_n}^\ell - g_{0_n}^\ell) \nu_{k_n}^{m,\ell} = (g_{m_1}^\ell - g_{0_1}^\ell) \nu_{k_1}^{m,\ell} + \sum_{A_\ell^t \in B_t / A_1^t} (g_{m_n}^\ell - g_{0_n}^\ell) \nu_{k_n}^{m,\ell},
\]

\[
\leq (g_{m_1}^\ell - g_{0_1}^\ell) \nu_{k_1}^{m,\ell} + \sum_{n \in \{2,3,4, \cdots, u_t\}} (g_{k_n}^\ell - g_{0_n}^\ell) \nu_{k_n}^{m,\ell},
\]

\[
= (\nu_{k_1}^{m,\ell})^2 + \sum_{n \in \{2,3,4, \cdots, u_t\}} (g_{k_n}^\ell - g_{0_n}^\ell) \nu_{k_n}^{m,\ell},
\]

where we get (a) from (39), and (b) follows from the fact that \(A_1^t \in B_t \subseteq G_x^\ell(2)\), and for any subset \(A_n^t \in G_x^\ell(2)\), \(g_{m_n}^\ell - g_{0_n}^\ell < \nu_{k_n}^{m,\ell}\) (by definition of \(G_x^\ell(2)\)).
By definition of $B_t$, the earliest time instant when an update $j \geq k_{nt}^f$ is completely transmitted by SRPT$^L$ (i.e., $r_{k_{nt}^f}^L$ is equal $\forall n \in \{1, 2, 3, \ldots, u_t\}$. Therefore, $r_{k_{nt}^f}^L = r_{k_{nt}^f}^L$, \(\forall n \in \{1, 2, 3, \ldots, u_t\}$. Thus, using Lemma 5, we get that $\forall n \in \{1, 2, 3, \ldots, u_t\}$, $r_{k_{nt}^f}^L = r_{k_{nt}^f}^L + \nu_{k_{nt}^f}^L \geq g_{k_{nt}^f}^L + \nu_{k_{nt}^f}^L$, which implies $(g_{k_{nt}^f}^L - g_{k_{nt}^f}^L) + \nu_{k_{nt}^f}^L \geq \nu_{k_{nt}^f}^L$. Since $k_{nt}^f < k_{nt}^f$ (for $n \geq 2$), $(g_{k_{nt}^f}^L - g_{k_{nt}^f}^L) < 0$. Therefore, $\nu_{k_{nt}^f}^L \geq \nu_{k_{nt}^f}^L$. Further, by definition of $k_{nt}^f$, at some time, SRPT begins to transmit updates $k_{nt}^f$. Thus, using Lemma 12, we get $\nu_{k_{nt}^f}^L \leq \nu_{k_{nt}^f}^L$, which implies $\nu_{k_{nt}^f}^L \leq \nu_{k_{nt}^f}^L$. Hence,

$$
\sum_{n \in \{2, 3, 4, \ldots, u_t\}} (g_{n_{nt}^f}^L - g_{n_{nt}^f}^L) \nu_{k_{nt}^f}^L \leq 2 \nu_{k_{nt}^f}^L \sum_{n \in \{2, 3, 4, \ldots, u_t\}} (g_{n_{nt}^f}^L - g_{n_{nt}^f}^L) \leq 2 \nu_{k_{nt}^f}^L (g_{k_{nt}^f}^L - g_{k_{nt}^f}^L),
$$

where (a) follows from the fact that $0^2 < k_{nt}^f < k_{nt}^f < k_{nt}^f < \cdots < 0^2 < k_{nt}^f$.

Again, by definition, $g_{k_{nt}^f}^L = r_{k_{nt}^f}^L (a) = g_{k_{nt}^f}^L + \nu_{k_{nt}^f}^L (b)$, where (a) is true because $k_{nt}^f \in A_t^f \in B_t$ and $k_{nt}^f \in A_t^f \in B_t$ both lie in same set $B_t$, while (b) follows because $\nu_{k_{nt}^f}^L = \nu_{k_{nt}^f}^L + d_{k_{nt}^f}^L \leq \nu_{k_{nt}^f}^L$ (Lemma 6). Thus, $(g_{k_{nt}^f}^L - g_{k_{nt}^f}^L) \leq 2 \nu_{k_{nt}^f}^L$. Substituting this result in (41), we get $\sum_{n \in \{2, 3, 4, \ldots, u_t\}} (g_{n_{nt}^f}^L - g_{n_{nt}^f}^L) \nu_{k_{nt}^f}^L \leq 4(\nu_{k_{nt}^f}^L)^2$, which together with (40) implies

$$
\sum_{A_t^f \in B_t} (g_{n_{nt}^f}^L - g_{n_{nt}^f}^L) \nu_{k_{nt}^f}^L \leq 5(\nu_{k_{nt}^f}^L)^2.
$$

From Lemma 8, we get that with an optimal offline policy $\pi^*$, the earliest time instant when the transmission of an update $j \geq k_{nt}^f$ completes is $g_{k_{nt}^f}^L + \nu_{k_{nt}^f}^L \geq g_{k_{nt}^f}^L + \nu_{k_{nt}^f}^L$. Thus, at any time $t \in (g_{k_{nt}^f}^L, g_{k_{nt}^f}^L + \nu_{k_{nt}^f}^L]$, $\lambda^*(t) \leq g_{k_{nt}^f}^L$, which implies that the AoI of $\pi^*$ at time $t \in (g_{k_{nt}^f}^L, g_{k_{nt}^f}^L + \nu_{k_{nt}^f}^L]$ is $\Delta_{\pi^*}(t) = t - \lambda^*(t) \geq t - g_{k_{nt}^f}^L$. Hence,

$$
\int_{g_{k_{nt}^f}^L}^{g_{k_{nt}^f}^L + \nu_{k_{nt}^f}^L} \Delta_{\pi^*}(t) \Delta_{\pi^*}(t) \geq \frac{(\nu_{k_{nt}^f}^L)^2}{2}.
$$

Comparing (42) and (43), we get $\sum_{A_t^f \in B_t} (g_{n_{nt}^f}^L - g_{n_{nt}^f}^L) \nu_{k_{nt}^f}^L \leq 10 \int_{g_{k_{nt}^f}^L}^{g_{k_{nt}^f}^L + \nu_{k_{nt}^f}^L} \Delta_{\pi^*}(t) \Delta_{\pi^*}(t)$.

### H.2 Time intervals $(g_{k_{nt}^f}^L, g_{k_{nt}^f}^L + \nu_{k_{nt}^f}^L]$ and $(g_{k_{nt}^f}^L + 2, g_{k_{nt}^f}^L + \nu_{k_{nt}^f}^L + 2]$ are disjoint, $\forall n$. Proof. By definition, $B_1, B_2, \cdots$ are such that $r_{B_1}^L < r_{B_2}^L < \cdots$, while $r_{B_t}^L = r_{k_{nt}^f}^L, \forall n$ (since $r_{k_{nt}^f}^L$ denotes the earliest time when an update $j \geq k_{nt}^f$ is completely transmitted by SRPT$^L$, while $k_{nt}^f$ denotes the $k_{nt}^f$th update in the subset $A_t^f$). Therefore, $r_{k_{nt}^f}^L < r_{k_{nt}^f}^L + 1 < r_{k_{nt}^f}^L + 2, \forall n$, which also implies that $g_{k_{nt}^f}^L < g_{k_{nt}^f}^L + 1 < g_{k_{nt}^f}^L + 2, \forall n$. Therefore, to show that the intervals $(g_{k_{nt}^f}^L, g_{k_{nt}^f}^L + \nu_{k_{nt}^f}^L]$ and $(g_{k_{nt}^f}^L + 2, g_{k_{nt}^f}^L + \nu_{k_{nt}^f}^L + 2]$ are disjoint, we show that $g_{k_{nt}^f}^L + \nu_{k_{nt}^f}^L \leq g_{k_{nt}^f}^L + 2$ using contradiction.

Let $g_{k_{nt}^f}^L + \nu_{k_{nt}^f}^L > g_{k_{nt}^f}^L + 2$. From Lemma 5, the earliest time by which SRPT$^L$ can completely transmit an update $j \geq k_{nt}^f$ is $r_{k_{nt}^f}^L \geq g_{k_{nt}^f}^L + \nu_{k_{nt}^f}^L$. Therefore, $r_{k_{nt}^f}^L > g_{k_{nt}^f}^L + 2 + \nu_{k_{nt}^f}^L$, which implies that at time $r_{k_{nt}^f}^L$, source has update $k_{nt}^f$. Since SRPT$^L$ begins to transmit an update at time $t$ only if its generation time is latest, we get that at time $t \geq r_{k_{nt}^f}^L$, SRPT only transmits updates $j \geq k_{nt}^f + 2$. However, after time $r_{k_{nt}^f}^L$, directly transmitting an update
\[ j \geq k_2^{\ell+2} \] would imply that \( r_{k_1}^{L,\ell+1} = r_{k_1}^{L,\ell+2} \), which is in contradiction to the definitions of \( B_{\ell+1} \) and \( B_{\ell+2} \). Therefore, the assumption that \( g_{k_1}^{\ell} + \nu_{k_1}^{\text{min, }\ell} > g_{k_1}^{\ell+2} \) must be wrong. Hence, we get that \( g_{k_1}^{\ell} + \nu_{k_1}^{\text{min, }\ell} \leq g_{k_1}^{\ell+2} \).
