Abstract

We study the online bin packing problem under a stochastic setting. In the bin packing problem, we are given n items with sizes in $(0, 1]$ and the goal is to pack them into the minimum number of unit-sized bins. First, we study bin packing under the i.i.d. model, where item sizes are sampled independently and identically from a distribution in $(0, 1]$. Both the distribution and the total number of items are unknown. The items arrive one by one and their sizes are revealed upon their arrival and they must be packed immediately and irrevocably in bins of size 1. We provide a simple meta-algorithm that takes an offline α -asymptotic approximation algorithm and provides a polynomial-time $(\alpha + \varepsilon)$ -competitive algorithm for online bin packing under the i.i.d. model, where $\varepsilon > 0$ is a small constant. Using the AFPTAS for offline bin packing, we thus provide a linear time $(1 + \varepsilon)$ -competitive algorithm for online bin packing under i.i.d. model, thus settling the problem.

We then study the random-order model, where an adversary specifies the items, but the order of arrival of items is drawn uniformly at random from the set of all permutations of the items. Kenyon’s seminal result [SODA’96] showed that the Best-Fit algorithm has a competitive ratio of at most $3/2$ in the random-order model, and conjectured the ratio to be ≈ 1.15 . However, it has been a long-standing open problem to break the barrier of $3/2$ even for special cases. Recently, Albers et al. [Algorithmica’21] showed an improvement to $5/4$ competitive ratio in the special case when all the item sizes are greater than $1/3$. For this special case, we settle the analysis by showing that Best-Fit has a competitive ratio of 1. We also make further progress by breaking the barrier of $3/2$ for the *3-Partition* problem, a notoriously hard special case of bin packing, where all item sizes lie in $(1/4, 1/2]$.

1 Introduction

Bin Packing (BP) is a fundamental NP-hard combinatorial optimization problem. In BP, we are given a set of items $I := (x_1, x_2, \dots, x_n)$ with their associated weights (also called

* A part of this work was done when Nikhil and Rajni were summer interns at the Indian Institute of Science, Bengaluru. Rajni’s internship was supported by ACM India Anveshan Setu Fellowship.

sizes) x_i 's in $(0, 1]$ and the goal is to partition them into the minimum number of sets (bins) such that the total weight of each set is at most 1. The problem has numerous applications in logistics, scheduling, cutting stock, etc. [10]. Theoretically, bin packing has been the cornerstone for approximation and online algorithms and the study of the problem has led to the development of several interesting techniques [31, 15, 33].

Generally, the performance guarantee of an offline (resp. online) bin packing algorithm \mathcal{A} is measured by asymptotic approximation ratio (AAR) (resp. competitive ratio (CR)). Let $\text{Opt}(I)$ and $\mathcal{A}(I)$ are the objective values returned by the optimal (offline) algorithm and algorithm \mathcal{A} , respectively, on input I . Then AAR (resp. CR) is defined as $R_{\mathcal{A}}^{\infty} := \limsup_{m \rightarrow \infty} \left(\sup_{I: \text{Opt}(I)=m} \frac{\mathcal{A}(I)}{\text{Opt}(I)} \right)$. Note that $R_{\mathcal{A}}^{\infty}$ focuses on instances where $\text{Opt}(I)$ is large and avoids pathological instances with large approximation ratios where $\text{Opt}(I)$ is small.

Best-Fit (BF), First-Fit (FF), and Next-Fit (NF) are the three most commonly used algorithms for BP. Given x_i as the present item to be packed, they work as follows:

- BF: Pack x_i into the *fullest possible* bin; open a new bin if necessary.
- FF: Pack x_i into the *first possible* bin; open a new bin if necessary.
- NF: Pack x_i into the *most recently opened* bin; open a new bin if necessary.

Johnson et al. [28] studied several heuristics for bin packing such as Best-Fit (BF), First-Fit (FF), Best-Fit-Decreasing (BFD), First-Fit-Decreasing (FFD) and showed their (asymptotic) approximation guarantees to be $17/10$, $17/10$, $11/9$, $11/9$, resp. Bekesi et al. [7] gave an $O(n)$ time $5/4$ -asymptotic approximation algorithm. Another $O(n \log n)$ time algorithm is Modified-First-Fit-Decreasing (MFFD) [29] which attains an AAR of $71/60 \approx 1.1834$. Vega and Lueker [15] gave an asymptotic fully polynomial-time approximation scheme (AFPTAS) for BP: For any $1/2 > \varepsilon > 0$, it returns a solution with at most $(1 + \varepsilon)\text{Opt}(I) + O(1)$ ¹ bins in time $C_{\varepsilon} + Cn \log 1/\varepsilon$, where C is an absolute constant and C_{ε} depends only on ε . Karmarkar and Karp [31] gave an algorithm that returns a solution using $\text{Opt}(I) + O(\log^2 \text{Opt}(I))$ bins. The present best approximation is due to Hoberg and Rothvoss [25] which returns a solution using $\text{Opt}(I) + O(\log \text{Opt}(I))$ bins.

3-Partition problem is a notoriously hard special case of BP where all item sizes are larger than $1/4$. Eisenbrand et al. [17] mentioned that “much of the hardness of bin packing seems to appear already in the special case of 3-Partition when all item sizes are in $(1/4, 1/2]$ ”. This problem has deep connections with Beck’s conjecture in discrepancy theory [45, 38]. In fact, Rothvoss [25] conjectured that these 3-Partition instances are indeed the hardest instances for bin packing and the additive integrality gap of the bin packing configuration LP for these 3-Partition instances is already $\Theta(\log n)$.

In online BP, items appear one by one and are required to be packed immediately and irrevocably. Lee and Lee [33] presented the Harmonic algorithm with competitive ratio $T_{\infty} \approx 1.691$, which is optimal for $O(1)$ space algorithms. For general online BP, the present best upper and lower bounds for the CR are 1.57829 [4] and 1.54278 [5], respectively.

In this paper, we focus on online BP under a stochastic setting called the *i.i.d. model* [11] where the input items are sampled from a sequence of independent and identically distributed (i.i.d.) random variables. Here, the performance of an algorithm is measured by the expected competitive ratio (ECR) $ER_{\mathcal{A}} := \mathbb{E}[\mathcal{A}(I_n(F))]/\mathbb{E}[\text{Opt}(I_n(F))]$, where $I_n(F) := (X_1, X_2, \dots, X_n)$ is a list of n random variables drawn i.i.d. according to some unknown distribution F with support in $(0, 1]$. Mostly, bin packing has been studied under continuous

¹ In bin packing and related problems, the accuracy parameter ε is assumed to be a constant. Here, the term $O(1)$ hides some constants depending on ε .

uniform (denoted by $U[a, b], 0 \leq a < b \leq 1$, where item sizes are chosen uniformly from $[a, b]$) or discrete uniform distributions (denoted by $U\{j, k\}, 1 \leq j \leq k$, where item sizes are chosen uniformly from $\{1/k, 2/k, \dots, j/k\}$). For $U[0, 1]$, Coffman et al. [13] showed that NF has an ECR of $4/3$ and Lee and Lee [34] showed that the Harmonic algorithm has an ECR of $\pi^2/3 - 2 \approx 1.2899$. Interestingly, Bentley et al. [8] showed that the ECR of FF as well as BF converges to 1 for $U[0, 1]$. It was later shown that the expected wasted space (i.e., the number of needed bins minus the total size of items) is $\Theta(n^{2/3})$ for First-Fit [44, 12] and $\Theta(\sqrt{n} \log^{3/4} n)$ for Best-Fit [44, 35]. Rhee and Talagrand [42] exhibited an algorithm that w.h.p. achieves a packing in $\text{Opt} + O(\sqrt{n} \log^{3/4} n)$ bins for any distribution F on $(0, 1]$. However, note that their competitive ratio can be quite bad when $\text{Opt} \ll n$. A distribution F is said to be *perfectly packable* if the expected wasted space in the optimal solution is $o(n)$ (i.e., nearly all bins in an optimal packing are almost fully packed). Csirik et al. [14] studied the Sum-of-Squares (SS) algorithm and showed that for any perfectly packable distribution, the expected wasted space is $O(\sqrt{n})$. However, for distributions that are not perfectly packable, the SS algorithm has an ECR of at most 3 and can have an ECR of $3/2$ in the worst-case [14]. For any discrete distribution, they gave an algorithm with an ECR of 1 that runs in pseudo-polynomial time in expectation. Gupta et al. [24] also obtained similar $o(n)$ expected wasted space guarantee by using an algorithm inspired by the interior-point (primal-dual) solution of the bin packing LP. However, it remains an open problem to obtain a polynomial-time $(1 + \varepsilon)$ -competitive algorithm for online bin packing under the i.i.d. model for arbitrary general distributions. In fact, the present best polynomial-time algorithm for bin packing under the i.i.d. model is BF which has an ECR of at most $3/2$. However, Albers et al. [1] showed that BF has an ECR ≥ 1.1 even for a simple distribution: when each item has size $1/4$ with probability $3/5$ and size $1/3$ with probability $2/5$.

We also study the *random-order model*, where the adversary specifies the items, but the arrival order is permuted uniformly at random. The performance measure in this model is called asymptotic random order ratio (ARR): $RR_{\mathcal{A}}^{\infty} := \limsup_{m \rightarrow \infty} \left(\sup_{I: \text{Opt}(I)=m} (\mathbb{E}[\mathcal{A}(I_{\sigma})] / \text{Opt}(I)) \right)$. Here, σ is drawn uniformly at random from \mathcal{S}_n , the set of permutations of n elements, and $I_{\sigma} := (x_{\sigma(1)}, \dots, x_{\sigma(n)})$ is the permuted list. Random-order model generalizes the i.i.d. model [1], thus the lower bounds in the random-order model can be obtained from the i.i.d. model. Kenyon in her seminal paper [32] studied Best-Fit under random-order and showed that $1.08 \leq RR_{BF}^{\infty} \leq 3/2$. She conjectured that $RR_{BF}^{\infty} \leq 1.15$. The conjecture, if true, raises the possibility of a better alternate practical offline algorithm: first shuffle the items randomly, then apply Best-Fit. This then beats the AAR of $71/60$ of the present best practical algorithm MFFD. The conjecture has received a lot of attention in the past two decades and yet, no other polynomial-time algorithm is known with a better ARR than BF. Coffman et al. [30] showed that $RR_{NF}^{\infty} = 2$. Fischer and Röglin [21] achieved analogous results for Worst-Fit [27] and Smart-Next-Fit [39]. Recently, Fischer [9] presented an exponential-time algorithm, claiming an ARR of $(1 + \varepsilon)$.

Monotonicity is a natural property of BP algorithms, which holds if the algorithm never uses fewer bins to pack \hat{I} when compared I , where \hat{I} is obtained from I by increasing the item sizes. Murgolo [37] showed that while NF is monotone, BF and FF are not.

Several other problems have been studied under the i.i.d. model and the random-order model [16, 23, 18, 22, 19, 2, 20, 36, 24].

1.1 Our Contributions

Bin packing under the i.i.d. model: We achieve near-optimal performance guarantee for the bin packing problem under the i.i.d. model, thus settling the problem. For any arbitrary unknown distribution F on $(0, 1]$, we give a meta-algorithm (see Algorithm 1) that takes an α -asymptotic approximation algorithm as input and provides a polynomial-time $(\alpha + \varepsilon)$ -competitive algorithm. Note that both the distribution F as well as the number of items n are unknown in this case.

► **Theorem 1.** *Let $\varepsilon \in (0, 1)$ be a constant parameter. For online bin packing under the i.i.d. model, where n items are sampled from an unknown distribution F , given an offline algorithm \mathcal{A}_α with an AAR of α and runtime $\beta(n)$, there exists a meta-algorithm (Algorithm 1) which returns a solution with an ECR of $(\alpha + \varepsilon)$ and runtime $O(\beta(n))$.²*

Using an AFPTAS for bin packing (e.g. [15]) as \mathcal{A}_α , we obtain the following corollary.

► **Corollary 2.** *Using an AFPTAS for bin packing as \mathcal{A}_α in Theorem 1, we obtain an algorithm for online bin packing under the i.i.d. model with an ECR of $(1 + \varepsilon)$ for any $\varepsilon \in (0, 1/2)$.*

Most algorithms for bin packing under the i.i.d. model are based on the following idea. Consider a sequence of $2k$ items where each item is independently drawn from an unknown distribution F , and let \mathcal{A} be a packing algorithm. Pack the first k items using \mathcal{A} ; denote the packing by \mathcal{P}' . Similarly, let \mathcal{P}'' be the packing of the next k items using \mathcal{A} . Since each item is drawn independently from F , both \mathcal{P}' and \mathcal{P}'' have the same properties in expectation; in particular, the expected number of bins used in \mathcal{P}' and \mathcal{P}'' are the same. Thus, intuitively, we want to use the packing \mathcal{P}' as a proxy for the packing \mathcal{P}'' . However, there are two problems. First, we do not know n , which means that there is no way to know what a good sample size is. Second, we need to show the stronger statement that w.h.p. $\mathcal{P}' \approx \mathcal{P}''$. Note that the items in \mathcal{P}' and \mathcal{P}'' are expected to be similar, but they may not be the same. So, it is not clear which item in \mathcal{P}' is to be used as a proxy for a newly arrived item in the second half. Due to the online nature, erroneous choice of proxy items can be quite costly. Different algorithms handle this problem in different ways. Some algorithms exploit the properties of particular distributions, some use exponential or pseudo-polynomial time, etc.

Rhee and Talagrand [41, 42] used *upright matching* to decide which item can be considered as a proxy for a newly arrived item. They consider the model packing \mathcal{P}_k of the first k items (let's call these the proxy items) using an offline algorithm. With the arrival of each of the next k items, they take a proxy item at random and pack it according to the model packing. Then, they try to fit in the real item using upright matching. They repeat this process until the last item is packed. However, they could only show a guarantee of $\text{Opt} + O(\sqrt{n} \log^{3/4} n)$. The main drawback of [42] is that their ECR can be quite bad if $\text{Opt} \ll n$ (say, $\text{Opt} = \sqrt{n}$). One of the reasons for this drawback is that they don't distinguish between small and large items; when there are too many small items, the ECR blows up.

Using a similar approach, Fischer [9] obtained a $(1 + \varepsilon)$ -competitive randomized algorithm for the random-order model, but it takes exponential time, and the analysis is quite complicated. The exponential time was crucial in finding the optimal packing which was then used as a good proxy packing. However, prior to our work, no polynomial-time algorithm existed which achieves a $(1 + \varepsilon)$ competitive ratio.

² As mentioned in an earlier footnote, the $O(\cdot)$ notation hides some constants depending on ε here.

To circumvent these issues, we treat large and small items separately. However, a straightforward adaptation faces several technical obstacles. Thus our analysis required intricate applications of concentration inequalities and sophisticated use of upright matching. First, we consider the semi-random case when we know n . Our algorithm works in stages. For a small constant $\delta \in (0, 1]$, the first stage contains only $\delta^2 n$ items. These items give us an estimate of the distribution. If the packing does not contain too many large items, we show that the simple Next-Fit algorithm suffices for the entire input. Otherwise, we use a proxy packing of the set of first $\delta^2 n$ items to pack the next $\delta^2 n$ items. In the process, we pack the small and large items differently. Then we use the proxy packing of the first $2\delta^2 n$ items to pack the next $2\delta^2 n$ items and so on. In general, we use the proxy packing of the first $2^i \delta^2 n$ items to pack the next $2^i \delta^2 n$ items.

Finally, we get rid of the assumption that we know n using a doubling trick (we guess n first and keep doubling the guess if it turns out to be incorrect). However, there are several difficulties (e.g. input stopping midway of two consecutive guesses, large wasted space in the past stages). Yet, with involved technical adaptations, we can handle them (see Section 2.2 and Appendix A.5).

Our algorithm is simple, polynomial-time (in fact, $O(n)$ time), and achieves essentially the best possible competitive ratio. It is relatively simpler to analyze when compared to Fischer’s algorithm [9]. Also, unlike the algorithms of Rhee and Talagrand [42] as well as Fischer [9], our algorithm is deterministic. This is because, unlike their algorithms, instead of taking proxy items at random, we pack all the proxy items before the start of a stage and try to fit in the real items as they come. This makes our algorithm deterministic. Our algorithm is explained in detail in Section 2.1. The nature of the meta-algorithm provides flexibility and ease of application. See Table 1 for the performance guarantees obtained using different offline algorithms.

See Section 2 for the details of the proof and the description of our algorithm. In fact, our algorithm can easily be generalized to d -dimensional online vector packing [6], a multidimensional generalization of bin packing. See Section C in the Appendix for a $d(\alpha + \varepsilon)$ competitive algorithm for d -dimensional online vector packing where the i^{th} item X_i can be seen as a tuple $(X_i^{(1)}, X_i^{(2)}, \dots, X_i^{(d)})$ where each $X_i^{(j)}$ is independently sampled from an unknown distribution $\mathcal{D}^{(j)}$.

Bin packing under the random-order model: Next, we study BP under the random-order model. Recently, Albers et al. [1] showed that BF is monotone if all the item sizes are greater than $1/3$. Using this result, they showed that in this special case, BF has an ARR of at most $5/4$. We show that, somewhat surprisingly, in this case, BF actually has an ARR of 1 (see Section 3.1 for the detailed proof).

► **Theorem 3.** *For online bin packing under the random-order model, Best-Fit achieves an asymptotic random-order ratio of 1 when all the item sizes are in $(1/3, 1]$.*

Next, we study the 3-partition problem, a special case of bin packing when all the item sizes are in $(1/4, 1/2]$. This is known to be an extremely hard case [25]. Albers et al. [1] mentioned that “it is sufficient to have one item in $(1/4, 1/3]$ to force Best-Fit into anomalous behavior.” E.g., BF is non-monotone in the presence of items of size less than $1/3$. Thus the techniques of [1] do not extend to the 3-Partition problem. We break the barrier of $3/2$ in this special case, by showing that BF attains an ARR of ≈ 1.4941 .

► **Theorem 4.** *For online bin packing under the random-order model, Best-Fit achieves an asymptotic random-order ratio of ≈ 1.4941 when all the item sizes are in $(1/4, 1/2]$.*

\mathcal{A}_α	Time Complexity	Expected Competitive Ratio
AFPTAS [15]	$O(C_\varepsilon + Cn \log 1/\varepsilon)$	$(1 + \varepsilon)$
Modified-First-Fit-Decreasing [29]	$O(n \log n)$	$(71/60 + \varepsilon)$
Best-Fit-Decreasing [26]	$O(n \log n)$	$(11/9 + \varepsilon)$
First-Fit-Decreasing [26]	$O(n \log n)$	$(11/9 + \varepsilon)$
Next-Fit-Decreasing [3]	$O(n \log n)$	$(T_\infty + \varepsilon)$
Harmonic [33]	$O(n)$	$(T_\infty + \varepsilon)$
Next-Fit	$O(n)$	$(2 + \varepsilon)$

■ **Table 1** Analysis of Algorithm 1 depending on \mathcal{A}_α . In the first row, C is an absolute constant and C_ε is a constant that depends on ε .

We prove Theorem 4 in Section 3.2. As 3-partition instances are believed to be the hardest instances for bin packing, our result gives a strong indication that the ARR of BF might be strictly less than $3/2$.

2 Online Bin Packing Problem under the i.i.d. Model

In this section, we provide the meta algorithm as described in Theorem 1. For the ease of presentation, we split this into two parts. In Section 2.1, we assume a semi-random model, i.e., we assume that the number of items n is known beforehand and design an algorithm. Later, in Section 2.2, we get rid of this assumption.

Let the underlying distribution be F . Without loss of generality, we assume that the support set of F is a subset of $(0, 1]$. For any set of items J , we define $\mathcal{W}(J)$ as the sum of weights of all the items in J . For any $k \in \mathbb{N}_+$, we denote the set $\{1, 2, \dots, k\}$ by $[k]$. Let $\varepsilon \in (0, 1)$ be a constant parameter and let $0 < \delta < \varepsilon/8$ be a constant. Let \mathcal{A}_α be an offline algorithm for bin packing with an AAR of $\alpha > 1$ and let Opt denote the optimal algorithm. For any $i \in [n]$, we call x_i to be a *large* item if $x_i \geq \delta$ and a *small* item otherwise. Let I_ℓ and I_s denote the set of large and small items in I , respectively.

2.1 Algorithm Assuming that the Value of n is Known

We now describe our algorithm which assumes the knowledge of the number of items. For simplicity, in this section we assume both n and $1/\delta^2$ to be powers of 2. Otherwise, we can round down $\delta \in [1/2^{i+1}, 1/2^i), i \in \mathbb{N}$ to $1/2^{i+1}$. Also, we will anyway get rid of the assumption on the knowledge of n in the next subsection, and there we do not need n to be a power of 2. We denote this algorithm by Alg. First, we give a high level idea of the algorithm. We divide the entire input into stages as follows: we partition the input set I into $m := (\log(1/\delta^2) + 1)$ stages T_0, T_1, \dots, T_{m-1} . The zeroth stage T_0 , called the *sampling stage*, contains the first $\delta^2 n$ items, i.e., $x_1, x_2, \dots, x_{\delta^2 n}$. For $j \in [m-1]$, T_j contains the items with index starting from $2^{j-1}\delta^2 n + 1$ till $2^j\delta^2 n$. In essence, T_0 contains the first $\delta^2 n$ items, T_1 contains the next $\delta^2 n$ items, T_2 contains the next $2\delta^2 n$ items, and so on. Note that the number of stages m is a constant. In any stage T_j , we denote the set of large items and small items by L_j and S_j , respectively. For $j \in [m-1]$, let \overline{T}_j denote the set of items which have arrived before the stage T_j , i.e., $\overline{T}_j = T_0 \cup T_1 \cup \dots \cup T_{j-1}$. Similarly, we define \overline{L}_j and \overline{S}_j as the set of large items and small items, respectively, in \overline{T}_j . Note that for any $j \in [m-1]$, $|T_j| = |\overline{T}_j|$ and since all the items are sampled independently from the same distribution, we know that with high probability, the optimal solutions of T_j and \overline{T}_j are quite

similar. Since \overline{T}_j would have arrived before T_j , we compute an almost optimal packing of \overline{T}_j (in an offline manner) and use it as a blueprint to pack T_j .

The algorithm is as follows: first, we pack T_0 , the sampling stage using Next-Fit. The sampling stage contains only a small but a constant fraction of the entire input set; hence it uses only a few number of bins when compared to the final packing but at the same time provides a good estimate of the underlying distribution. If the number of large items in the sampling stage is at most $\delta^3 \mathcal{W}(T_0)$, then we continue using Next-Fit for the rest of the entire input too. Intuitively, NF performs well in this case as most of the items are small. Thus, from now on, let us assume otherwise. Now assume that we are at an intermediate point where \overline{T}_j has arrived and T_j is about to arrive ($j \geq 1$). We create D_j , the set of *proxy* items, which is just a copy of \overline{T}_j . We pack D_j using \mathcal{A}_α . Let this packing be denoted by \mathcal{P}_j . Let $B_j^{(k)}$ denote the k^{th} bin in the packing \mathcal{P}_j . We iterate over k and remove all the small items in the bin $B_j^{(k)}$ and create a slot in the free space of $B_j^{(k)}$. We call this slot to be an *S-slot*. When an item $x_i \in T_j$ arrives, we check if x_i is small or large

- If x_i is small, we pack it in one of the *S-slots* greedily, using Next-Fit. If it doesn't fit in any of the *S-slots*, then we create a new bin with only one *S-slot* spanning the entire bin (so, this bin will only be used to pack small items), and pack it there.
- If x_i is large, we remove the smallest proxy item with a size more than x_i in the packing \mathcal{P}_j and pack it there. If no such proxy item exists, we open a new bin, pack x_i in there and close it, meaning that it will not be used to pack any further items.

After T_j is packed completely, we just discard the proxy items in the packing that haven't been replaced and move to the next stage. For more formal details and pseudocode for the algorithm, please refer to Algorithm 1.

We will proceed to analyze the algorithm. But first, we will discuss stochastic upright matching and a standard result on it. Using a standard probabilistic concentration lemma, we will formulate a few lemmas which are going to be very important for the analysis of the algorithm.

Stochastic Upright Matching. Rhee and Talagrand [43] studied stochastic upright matching problem in the context of analysis of bin packing algorithms. Consider a set $P = \{(x_i, y_i)\}_{i \in [2n]}$ of $2n$ points where each x_i is either $+1$ or -1 with equal probability and y_1, y_2, \dots, y_{2n} are sampled according to an i.i.d. distribution. We can define a bipartite graph \mathcal{G} as follows: the vertex set is P , viewed as a set of points in $\mathbb{R} \times \mathbb{R}$. Two points $P_1 = (x_1, y_1), P_2 = (x_2, y_2)$ share an edge iff $x_1 = 1, x_2 = -1$ and $y_1 \geq y_2$.

The objective of the problem is to find a maximum matching in \mathcal{G} or, in other words, minimize the number of unmatched points which we denote by $U(P)$. We denote this matching variant by \mathcal{M} . The following lemma shows that w.h.p., the number of unmatched points is $O(\sqrt{n}(\log n)^{3/4})$. The proof of the lemma follows from Lemma 3.1 in [43].

► **Lemma 5.** [43] *Let P be an instance for \mathcal{M} . Then there exist constants $a, C, K > 0$ such that, $\mathbb{P}[U(P) \geq K\sqrt{n}(\log n)^{3/4}] \leq C \exp(-a(\log n)^{3/2})$.*

Concentration Inequalities. Now we state the concentration inequalities.

► **Lemma 6 (Bernstein's Inequality).** *Let X_1, X_2, \dots, X_n be independent random variables such that each $X_i \in [0, 1]$. Then, for any $\lambda > 0$, the following inequality holds.*

$$\mathbb{P} \left[\left| \sum_{i=1}^n X_i - \sum_{i=1}^n \mathbb{E}[X_i] \right| \geq \lambda \right] \leq 2 \exp \left(- \frac{\lambda^2}{2(\sum_{i=1}^n \mathbb{E}[X_i] + \lambda/3)} \right).$$

The following lemma is a direct implication of the results of [42, 40].

■ **Algorithm 1** $\text{Alg}(x_1, x_2, \dots, x_n)$: A nearly optimal algorithm for online bin packing assuming that the number of items n is known before-hand

```

► **Lemma 7.** For any $t \in [n]$, let $I(1, t)$ denote the first t items of the input set I . Then there exist constants $K, a > 0$ such that, $\mathbb{P} [\text{Opt}(I(1, t)) \geq \frac{t}{n} \mathbb{E} [\text{Opt}(I)] + K\sqrt{n}(\log n)^{3/4}] \leq \exp(-a(\log n)^{3/2})$.

The following lemmas are about how a property of a part of the input (say, the total size) compares to that of the entire input.

► **Lemma 8.** For an input set I of n items drawn from a distribution independently, for any arbitrary set $J \subseteq I$ we have, $\mathbb{P} \left[\left| \mathcal{W}(J) - \frac{|J|}{n} \mathbb{E} [\mathcal{W}(I)] \right| \geq \mathbb{E} [\mathcal{W}(I)]^{2/3} \right] \leq 2 \exp \left(-\frac{1}{3} \mathbb{E} [\mathcal{W}(I)]^{1/3} \right)$.

► **Lemma 9.** Let I be an input set of n items drawn from a distribution independently and let J be any subset of I . Suppose J_ℓ (resp. I_ℓ) denote the set of large items in J (resp. I). Then we have, $\mathbb{P} \left[\left| |J_\ell| - \frac{|J|}{n} \mathbb{E} [|I_\ell|] \right| \geq \mathbb{E} [\mathcal{W}(I)]^{2/3} \right] \leq 2 \exp \left(-\frac{\delta}{3} \mathbb{E} [\mathcal{W}(I)]^{1/3} \right)$.

► **Lemma 10.** For any $t \in \{1, 2, \dots, n\}$, Suppose $I(1, t)$ denote the first t items of the input set I . Then there exist constants $C, a > 0$ such that with probability at least $1 - \exp(-a(\log \mathbb{E} [\text{Opt}(I)])^{1/3})$, we have $\text{Opt}(I(1, t)) \leq (1 + 2\delta) \frac{t}{n} \mathbb{E} [\text{Opt}(I)] + C \mathbb{E} [\text{Opt}(I)]^{2/3}$.

Lemma 7 (resp. Lemmas 8 and 9) intuitively states that the optimal solution for (resp. the weight of the items of, and the number of large items in) a part of the input is almost a linear function of the length of the part. This makes sense because each item comes from the same distribution. Lemma 10 further tries to improve on Lemma 7 by bounding the lower order terms in terms of $\mathbb{E} [\text{Opt}(I)]$ instead of n while losing only a small factor of $1 + 2\delta$. This is crucial since we need to bound the number of additional bins used by our algorithm in terms of $\mathbb{E} [\text{Opt}(I)]$ and not in terms of n . We give the proofs of Lemmas 7–10 in Appendix A. As mentioned, Lemma 7 follows from [42, 40]. Lemmas 8 and 9 are simple applications of Bernstein’s inequality. The high-level proof of Lemma 10 goes as follows: first we consider the optimal packing of the large items in $I(1, t)$, then we pack the small items in $I(1, t)$ greedily. If the small items open new bins then it means that all the bins (except one) are filled up to a level at least $1 - \delta$. Otherwise, we don’t use any extra bins. So, $\text{Opt}(I(1, t)) \leq \max\{\text{Opt}(I_\ell(1, t)), (1 + 2\delta)\mathcal{W}(I(1, t)) + 1\}$. Then we use Lemmas 7, 8 and 9 to prove Lemma 10.

With these helpful lemmas, we now proceed to analyze the algorithm. We split the analysis into the following two cases: when $|L_0| \leq \delta^3 \cdot \mathcal{W}(T_0)$ and when $|L_0| > \delta^3 \cdot \mathcal{W}(T_0)$.

2.1.1 Case 1: $|L_0| \leq \delta^3 \cdot \mathcal{W}(T_0)$

Recall that in this case, we just continue with Next-Fit for all the remaining items. To bound the Next-Fit solution, we first consider the number of bins that contain at least one large item. For this, we bound the value of $|I_\ell|$. Then we consider the bins that contain only small items and bound this value in terms of weight of all items $\mathcal{W}(I)$.

▷ **Claim 11.** Let $K := \mathbb{E} [\text{Opt}(I)]$. For some positive constants C_1, C_2, a , we have that $\mathbb{P} [|I_\ell| \leq \delta \cdot \mathcal{W}(T_0) + C_1 K^{2/3}] \geq 1 - C_2 \exp(-aK^{1/3})$.

Proof. As the sampling stage contains $\delta^2 n$ items, $\mathbb{E} [|L_0|] = \delta^2 \mathbb{E} [|I_\ell|]$. From Lemma 9, we have $\mathbb{P} \left[|L_0| \leq \delta^2 \mathbb{E} [|I_\ell|] - \mathbb{E} [\mathcal{W}(I)]^{2/3} \right] \leq 2 \exp(-(\delta/3) \cdot (\mathbb{E} [\mathcal{W}(I)]^{1/3}))$, and $\mathbb{P} \left[|I_\ell| \geq \mathbb{E} [|I_\ell|] + \mathbb{E} [\mathcal{W}(I)]^{2/3} \right] \leq 2 \exp(-(\delta/3) \cdot \mathbb{E} [\mathcal{W}(I)]^{1/3})$. From the above inequalities we have, $|I_\ell| \leq \frac{1}{\delta^2} |L_0| + (1 + \frac{1}{\delta^2}) \mathbb{E} [\mathcal{W}(I)]^{2/3}$ with probability at least $1 - 4 \exp(-\frac{\delta}{3} \mathbb{E} [\mathcal{W}(I)]^{1/3})$. We can use the inequalities $\mathbb{E} [\text{Opt}(I)] \geq \mathbb{E} [\mathcal{W}(I)]$ and $|L_0| \leq \delta^3 \cdot \mathcal{W}(T_0)$ to conclude the proof of this claim. ◀

Now we bound the number of bins that are closed by small items. Note that Next-Fit fills each such bin up to a capacity at least $(1 - \delta)$. So, the number of such bins is at most $\frac{1}{1-\delta}\mathcal{W}(I)$ when all items are packed by Next-Fit. Also, there can be at most one bin that can be open. Thus combining all these results, (and using inequality $\frac{1}{1-\delta} \leq 1 + 2\delta$ for $\delta < \frac{1}{2}$) with high probability, $\text{NF}(I) \leq |I_\ell| + (1 + 2\delta)\mathcal{W}(I) + 1 \leq \delta \cdot \mathcal{W}(T_0) + (1 + 2\delta)\mathcal{W}(I) + K\mathbb{E}[\text{Opt}(I)]^{2/3}$, for some constant K .

Using Lemma 8, we get that with high probability, $\mathcal{W}(I) \leq \mathbb{E}[\mathcal{W}(I)] + \mathbb{E}[\mathcal{W}(I)]^{2/3}$. Using the facts $\mathcal{W}(I) \geq \mathcal{W}(T_0)$ and $\mathbb{E}[\text{Opt}(I)]/2 \leq \mathbb{E}[\mathcal{W}(I)] \leq \mathbb{E}[\text{Opt}(I)]$, we get,

$$\text{NF}(I) \leq (1 + 3\delta)\mathbb{E}[\text{Opt}(I)] + C_3\mathbb{E}[\text{Opt}(I)]^{2/3} \quad (1)$$

with probability of at least $1 - C_4 \exp(-a_1\mathbb{E}[\text{Opt}(I)]^{1/3})$ for some constants $C_3, C_4, a_1 > 0$. When the low probability event occurs, we can use the upper bound of $\text{NF}(I) \leq 2\text{Opt}(I) - 1$ to obtain the competitive ratio. Let $p = C_4 \exp(-a_1\mathbb{E}[\text{Opt}(I)]^{1/3})$.

$$\begin{aligned} \mathbb{E}[\text{NF}(I)] &\leq (1 - p) \left((1 + 3\delta)\mathbb{E}[\text{Opt}(I)] + K\mathbb{E}[\text{Opt}(I)]^{2/3} + 1 \right) + p(2\mathbb{E}[\text{Opt}(I)] - 1) \\ &= (1 + 3\delta + 2p)\mathbb{E}[\text{Opt}(I)] + o(\mathbb{E}[\text{Opt}(I)]) \end{aligned}$$

Since $p = o(1)$ when $\mathbb{E}[\text{Opt}(I)]$ tends to infinity, we obtain that the expected competitive ratio tends to at most $1 + 3\delta < 1 + \varepsilon$.

2.1.2 Case 2: $|L_0| > \delta^3 \cdot \mathcal{W}(T_0)$

We split our analysis in this case into two parts. We first analyze the number of bins used in the sampling stage T_0 and then analyze the number of bins used in the remaining stages.

Using Lemma 9, we obtain w.h.p. that $|L_0| \leq \delta^2\mathbb{E}[|I_\ell|] + \mathbb{E}[\mathcal{W}(I)]^{2/3}$. Hence,

$$\begin{aligned} \mathbb{E}[|I_\ell|] &\geq \frac{1}{\delta^2}|L_0| - \frac{1}{\delta^2}\mathbb{E}[\mathcal{W}(I)]^{2/3} \\ &\geq \delta\mathcal{W}(T_0) - \frac{1}{\delta^2}\mathbb{E}[\mathcal{W}(I)]^{2/3} && \text{(since } |L_0| > \delta^3 \cdot \mathcal{W}(T_0)\text{)} \\ &\geq \delta^3\mathbb{E}[\mathcal{W}(I)] - \left(\delta + \frac{1}{\delta^2}\right)\mathbb{E}[\mathcal{W}(I)]^{2/3} \end{aligned} \quad (2)$$

The last inequality follows from Lemma 8. For any $j \geq 1$, using $|T_j|/n \geq \delta^2$ and using Lemma 9, we get,

$$|L_j| \geq \delta^5\mathbb{E}[\mathcal{W}(I)] - (2 + \delta^3)\mathbb{E}[\mathcal{W}(I)]^{2/3} \quad (3)$$

Each of the Eqs. (2),(3) holds with a probability of at least $1 - C \exp(-a\mathbb{E}[\mathcal{W}(I)]^{1/3})$ for some constants $C, a > 0$.

Note that $\mathcal{W}(I) \geq \text{Opt}(I)/2$. So from now on we assume that there exist constants $C_1, C_2 > 0$ which depend on δ such that w.h.p. both the following inequalities hold.

$$\mathbb{E}[|I_\ell|] \geq C_1 \cdot \mathbb{E}[\text{Opt}(I)] \quad (4)$$

$$|L_j| \geq C_2 \cdot \mathbb{E}[\text{Opt}(I)] \quad (5)$$

- **Analysis of the Sampling Stage:** Recall that the number of items considered in the sampling phase is $\delta^2 n$. We will bound the number of large items and the weight of items in this stage using Bernstein's inequality.

1. Since sampling phase has $\delta^2 n$ items, $\mathbb{E}[|L_0|] = \delta^2 \mathbb{E}[|I_\ell|]$. By applying Bernstein's inequality for $X_1, X_2, \dots, X_{|T_0|}$ where X_i takes value 1 if x_i is large and 0 otherwise, we get,

$$\begin{aligned} \mathbb{P}[|L_0| \geq 2\delta^2 \mathbb{E}[|I_\ell|]] &= \mathbb{P}[|L_0| \geq \mathbb{E}[|L_0|] + \delta^2 \mathbb{E}[|I_\ell|]] \\ &\leq 2 \exp\left(-\frac{\delta^4 \mathbb{E}[|I_\ell|]^2}{2\mathbb{E}[|L_0|] + \frac{2}{3}\delta^2 \mathbb{E}[|I_\ell|]}\right) \leq 2 \exp\left(-\frac{1}{3}\delta^2 \mathbb{E}[|I_\ell|]\right) \\ &\leq 2 \exp(-a_1 \cdot \mathbb{E}[\text{Opt}(I)]) \quad (\text{from Equation (4)}) \end{aligned}$$

for some constant $a_1 > 0$. So, with high probability, $|L_0| \leq 2\delta^2 \mathbb{E}[|I_\ell|] \leq 2\delta \mathbb{E}[\text{Opt}(I)]$.

2. Similarly, $\mathbb{E}[\mathcal{W}(T_0)] = \delta^2 \mathbb{E}[\mathcal{W}(I)]$. By applying Bernstein's inequality for $X_1, X_2, \dots, X_{|T_0|}$ where X_i takes value x_i , we get,

$$\begin{aligned} \mathbb{P}[\mathcal{W}(T_0) \geq 2\delta^2 \mathbb{E}[\mathcal{W}(I)]] &= \mathbb{P}[\mathcal{W}(T_0) \geq \mathbb{E}[\mathcal{W}(S_0)] + \delta^2 \mathbb{E}[\mathcal{W}(I)]] \\ &\leq 2 \exp\left(\frac{-\delta^4 \mathbb{E}[\mathcal{W}(I)]^2}{2\delta^2 \mathbb{E}[\mathcal{W}(T_0)] + \frac{2}{3}\delta^2 \mathbb{E}[\mathcal{W}(I)]}\right) \\ &\leq 2 \exp\left(\frac{-\delta^2 \mathbb{E}[\mathcal{W}(I)]}{3}\right) \leq 2 \exp\left(\frac{-\delta^2 \mathbb{E}[\text{Opt}(I)]}{6}\right) \end{aligned}$$

So, with high probability we have, $\mathcal{W}(T_0) \leq 2\delta^2 \mathbb{E}[\mathcal{W}(I)] \leq 2\delta^2 \mathbb{E}[\text{Opt}(I)]$.

Since the number of bins opened by Next-Fit $\text{NF}(T_0)$ is at most $|L_0| + \frac{1}{1-\delta}\mathcal{W}(T_0) + 1$, using the bounds on the number of large items and weight of small items in sampling phase, w.h.p. we have,

$$\text{NF}(T_0) \leq 2\delta \mathbb{E}[\text{Opt}(I)] + \frac{2\delta^2}{1-\delta} \mathbb{E}[\text{Opt}(I)] \leq 4\delta \mathbb{E}[\text{Opt}(I)] \quad (6)$$

■ **Analysis of the Remaining Stages:** Consider any stage T_j ($j > 0$) after the sampling stage. Note that $|\overline{T}_j| = |T_j|$. A bin can be opened in three different ways.

1. When a new bin is opened while packing the set of proxy items D_j using \mathcal{A}_α (see the algorithm description in Section 2.1).
2. When a large item can't replace a proxy item and hence a new bin is opened for it.
3. When a small item can't fit in the set of S -slots and hence a new bin is opened with a single S -slot spanning the entire bin.

In our analysis, first we bound the number of bins opened by \mathcal{A}_α for proxy items; we use Lemma 10 to obtain this bound. Then we show that the number of large items which cannot replace a proxy item would be very small by using upright matching arguments (Lemma 5). For small items, we bound the number of new bins opened by using the fact that $\mathcal{W}(S_j)$ and $\mathcal{W}(\overline{S}_j)$ are very close which will be proved using Bernstein's inequality.

Now we analyze the number of bins opened in the *first way* (say A_{proxy}^j). This is nothing but the number of bins opened by \mathcal{A}_α to pack \overline{T}_j . Since, \mathcal{A}_α has an AAR of α , by using Lemma 10, we have,

$$\begin{aligned} A_{\text{proxy}}^j &= \mathcal{A}_\alpha(\overline{T}_j) \leq \alpha \text{Opt}(\overline{T}_j) + o(\text{Opt}(\overline{T}_j)) \\ &\leq \alpha(1+2\delta)(|\overline{T}_j|/n) \mathbb{E}[\text{Opt}(I)] + C_3 \mathbb{E}[\text{Opt}(I)]^{2/3} + o(\text{Opt}(I)) \quad (7) \end{aligned}$$

with probability at least $1 - \exp(-a_2 \log(\mathbb{E}[\text{Opt}(I)]))^{1/3}$, for some constants $C_3, a_2 > 0$.

We now bound the number of bins opened in the *second way*. Using Lemma 9, we get that w.h.p., $|\overline{L}_j| \geq \frac{\lfloor T_j \rfloor}{n} \mathbb{E}[|I_\ell|] - \mathbb{E}[\mathcal{W}(I)]^{2/3}$, and $|L_j| \leq \frac{\lfloor T_j \rfloor}{n} \mathbb{E}[|I_\ell|] + \mathbb{E}[\mathcal{W}(I)]^{2/3}$. Since $|\overline{T}_j| = |T_j|$ we have,

$$|L_j| \leq |\overline{L}_j| + 2\mathbb{E}[\mathcal{W}(I)]^{2/3}. \quad (8)$$

So, w.h.p. the number of large items in T_j doesn't exceed that of those in \overline{T}_j by a large number. Now consider the number of bins opened because there is no feasible proxy item that can be replaced. Let this number be A_{unmatch}^j . We can interpret this number as the number of unmatched items when we use the stochastic matching variant \mathcal{M} from [43] as follows. We can interpret each item $\bar{t} \in \overline{L}_j$ as a point $P_{\bar{t}} := (+1, \bar{t})$ and each point $t \in L_j$ as a point $P_t := (-1, t)$. For simplicity, let's call the points with $+1$ as their first coordinate as *plus* points and the points with -1 as their first coordinate as *minus* points. We match a point $P_{\bar{t}}$ with P_t iff t replaced \bar{t} in our algorithm. It is shown in [44] that such matching is always maximum. Hence the number of items that open new bins is at most the number of unmatched points in this maximum matching. There are two differences though. First, $|\overline{L}_j|$ may not be greater than $|L_j|$; but as we have shown, w.h.p, the difference can at most be $2\mathbb{E}[\mathcal{W}(I)]^{2/3}$. Secondly, in the matching variant \mathcal{M} , every point has equal chance to be a plus point or minus point. However, this is also inconsequential, since using concentration bounds for binomial random variables, we can show that the number of plus points/minus points lie in the range $(\mathbb{E}[|\overline{L}_j|] \pm \mathbb{E}[|\overline{L}_j|]^{2/3})$ w.h.p. Hence by Lemma 5, we obtain that there exist constants a_3, C_4, K_1 s.t.

$$\begin{aligned} \mathbb{P} \left[A_{\text{unmatch}}^j \geq K_1 \sqrt{|\overline{L}_j|} (\log |\overline{L}_j|)^{3/4} + 2\mathbb{E}[\mathcal{W}(I)]^{2/3} + 2\mathbb{E}[|\overline{L}_j|]^{2/3} \right] \\ \leq C_4 \exp \left(-a_3 (\log |\overline{L}_j|)^{3/2} \right) \end{aligned}$$

We can simplify the above inequality using Equations (5) and (8) and the fact that $\text{Opt}(I) \leq 2\mathcal{W}(I)$ to obtain that there exist constants $a_4, C_4, K_2 > 0$ such that,

$$\mathbb{P} \left[A_{\text{unmatch}}^j \geq K_2 \mathbb{E}[\text{Opt}(I)]^{2/3} \right] \leq C_4 \exp \left(-a_4 (\log \mathbb{E}[\text{Opt}(I)])^{3/2} \right) \quad (9)$$

The only part left is to bound the number of bins opened by small items in *third way*. Let this number be A_{small}^j . We will bound this by using the concentration of weights of small items in \overline{T}_j and T_j . Consider the random variables $X_1, X_2 \dots X_n$ where $X_i = 0$ if x_i is large, and $X_i = x_i$ otherwise. We have that $\mathcal{W}(S_j) = \sum_{X_i: x_i \in T_j} X_i$

and $\mathcal{W}(\overline{S}_j) = \sum_{X_i: x_i \in \overline{T}_j} X_i$. By applying Bernstein's inequality (similar to Lemma 8)

we get, $\mathcal{W}(S_j) \leq \frac{\lfloor T_j \rfloor}{n} \mathcal{W}(I_s) + \mathbb{E}[\mathcal{W}(I)]^{2/3}$, and $\mathcal{W}(\overline{S}_j) \geq \frac{\lfloor \overline{T}_j \rfloor}{n} \mathcal{W}(I_s) - \mathbb{E}[\mathcal{W}(I)]^{2/3}$ with a probability of at least $1 - C_5 \exp \left(-a_5 \mathbb{E}[\mathcal{W}(I)]^{1/3} \right)$ for some constants $C_5, a_5 > 0$. Combining both, we get,

$$\mathcal{W}(S_j) \leq \mathcal{W}(\overline{S}_j) + 2\mathbb{E}[\mathcal{W}(I)]^{2/3} \quad (10)$$

The initial allocated space for small items at the start of stage j in the packing \mathcal{P}_j is $\mathcal{W}(\overline{S}_j)$. Recall that $B_j^{(k)}$ denotes the k^{th} bin in the packing of \mathcal{P}_j . While packing the small items, if the S -slot in $B_j^{(k)}$ cannot accommodate a small item, this means that the remaining space in this S -slot is at most δ . So, the weight of small items which

overflow the space allocated in packing \mathcal{P}_j is at most $\mathcal{W}(S_j) - \mathcal{W}(\overline{S}_j) + \delta |\mathcal{P}_j|$ and this entire weight is packed in new bins opened exclusively for small items. Each of these bins (except possibly one) have an occupancy of at least $(1 - \delta)$. Since \mathcal{A}_α is α -approximation algorithm, $|\mathcal{P}_j| = \mathcal{A}_\alpha(\overline{T}_j) \leq \alpha \text{Opt}(\overline{T}_j) + o(\text{Opt}(I))$. Using Equations (7) and (10) we get,

$$\begin{aligned} A_{\text{small}}^j &\leq \frac{1}{1 - \delta} (\mathcal{W}(S_j) - \mathcal{W}(\overline{S}_j) + \delta \cdot \alpha \text{Opt}(\overline{T}_j) + o(\text{Opt}(I))) + 1 \\ &\leq 2\delta \cdot \alpha \frac{|\overline{T}_j|}{n} \mathbb{E} [\text{Opt}(I)] + C_3 \mathbb{E} [\text{Opt}(I)]^{2/3} + o(\text{Opt}(I)) \end{aligned} \quad (11)$$

with high probability. Combining Equations (7), (9), and (11), the number of bins, A_j , opened in the stage j is bounded as,

$$\begin{aligned} A_j &= A_{\text{proxy}}^j + A_{\text{unmatch}}^j + A_{\text{small}}^j \\ &\leq \alpha(1 + 4\delta) \frac{|\overline{T}_j|}{n} \mathbb{E} [\text{Opt}(I)] + C_6 \mathbb{E} [\text{Opt}(I)]^{2/3} + o(\text{Opt}(I)) \\ &\leq \alpha(1 + 4\delta) \frac{|\overline{T}_j|}{n} \mathbb{E} [\text{Opt}(I)] + C_6 \mathbb{E} [\text{Opt}(I)]^{2/3} + o(\text{Opt}(I)) \end{aligned} \quad (12)$$

w.h.p., for some constant C_6 . To bound the sum of all A_j s, first note that the number of “remaining stages” is $m - 1$ which is a constant dependent on δ . Hence, with high probability,

$$\begin{aligned} \sum_{j=1}^{m-1} A_j &\leq \alpha(1 + 4\delta) \sum_{j=1}^{m-1} \frac{|\overline{T}_j|}{n} \mathbb{E} [\text{Opt}(I)] + (m - 1) \cdot C_6 \mathbb{E} [\text{Opt}(I)]^{2/3} + o(\text{Opt}(I)) \\ &\leq \alpha(1 + 4\delta) \mathbb{E} [\text{Opt}(I)] + C_7 \mathbb{E} [\text{Opt}(I)]^{2/3} + o(\text{Opt}(I)) \end{aligned} \quad (13)$$

for some constant $C_7 > 0$ dependent on δ .

In the sampling phase, we have $\text{NF}(T_0) \leq 4\delta \mathbb{E} [\text{Opt}(I)]$ with high probability and in all the remaining phases we have $\sum_{j=1}^{m-1} A_j \leq \alpha(1 + 4\delta) \mathbb{E} [\text{Opt}(I)] + C_7 \mathbb{E} [\text{Opt}(I)]^{2/3} + o(\text{Opt}(I))$.

Combining both the results we get that w.h.p. the number of bins opened by Alg is,

$$\begin{aligned} \text{Alg}(I) &\leq \alpha(1 + 8\delta) \mathbb{E} [\text{Opt}(I)] + C_7 \mathbb{E} [\text{Opt}(I)]^{2/3} + o(\text{Opt}(I)) \\ &\leq \alpha(1 + \varepsilon) \mathbb{E} [\text{Opt}(I)] + C_7 \mathbb{E} [\text{Opt}(I)]^{2/3} + o(\text{Opt}(I)) \end{aligned} \quad (14)$$

In the low probability event when Equation (14) may not hold, we can bound $\text{Alg}(I)$ as follows. In the sampling stage, we have that $\text{Alg}(T_0) \leq 2\text{Opt}(I) - 1$. For the remaining stages, we bound the number of bins containing at least one large item and the number of bins containing only small items. Because we create a proxy packing at the start of each stage, each large item is packed at most m times. So, the number of bins containing at least one large item is at most $m |I_\ell|$. In each stage, with one possible exception, every bin opened which has only small items has an occupancy of at least $(1 - \delta)$. Combining over all the stages, the number of bins which contain only small items is at most $\frac{1}{1 - \delta} \mathcal{W}(I_s) + m$. Thus, we can bound the total number of bins used by Alg to be at most $2\text{Opt}(I) + m |I_\ell| + \frac{1}{1 - \delta} \mathcal{W}(I_s) + m$. On the other hand, we know that $\text{Opt}(I) \geq \mathcal{W}(I) \geq \delta |I_\ell| + \mathcal{W}(I_s)$. Hence, we obtain that $m |I_\ell| + \frac{1}{1 - \delta} \mathcal{W}(I_s) \leq \frac{m}{\delta(1 - \delta)} \text{Opt}(I)$. Combining all these, we obtain that

$$\text{Alg}(I) \leq \left(2 + \frac{m}{\delta(1 - \delta)} \right) \text{Opt}(I) + m \quad (15)$$

■ **Figure 1** Doubling trick visualized. We start off with an estimate of n to be n_0 and keep doubling it. The first and second super-stages contain n_0 items each. The third super-stage contains $2n_0$ items and so on. Each super-stage is packed individually using **Alg**. The stages in each super-stage are marked by \bullet (for simplicity, only the stages in the last two super-stages are marked). The \times mark indicates the point where the input abruptly stopped. Notice how the fifth stage of the last super-stage is not full. Just before packing this stage, **Alg** constructs a proxy packing of χ by using \mathcal{A}_α . But this is very lossy since χ is large compared to this last stage.

Now, to obtain the competitive ratio, suppose Equation (14) holds with probability $p(=1 - o(1))$. We combine Equations (14) and (15) similar to the case when $|L_0| \leq \delta^3 \cdot \mathcal{W}(T_0)$.

$$\begin{aligned} \mathbb{E}[\text{Alg}(I)] &\leq p(\alpha(1 + 8\delta)\mathbb{E}[\text{Opt}(I)] + o(\mathbb{E}[\text{Opt}(I)])) \\ &\quad + (1 - p) \left(\left(2 + \frac{m}{\delta(1 - \delta)} \right) \mathbb{E}[\text{Opt}(I)] + m \right) \\ &\leq \alpha(1 + \varepsilon)\mathbb{E}[\text{Opt}(I)] + o(\mathbb{E}[\text{Opt}(I)]) \quad (\text{since } 1 - p = o(1)) \end{aligned}$$

Scaling the initial value ε to ε/α before the start of the algorithm, we obtain a competitive ratio of $\alpha + \varepsilon$.

2.2 Getting Rid of the Assumption on the Knowledge of the Input Size

In this subsection, we will extend **Alg** for online bin packing with i.i.d. items to devise an algorithm that guarantees essentially the same competitive ratio without knowing the value of n . We denote this algorithm by **ImpAlg**.

We use a doubling trick as follows. We first guess the value of n to be a constant $n_0 := 1/\delta^3$. Then, we run **Alg** until $\min\{n, n_0\}$ items arrive (here, if $\min\{n, n_0\} = n$, then it means that the input stream has ended). If $n > n_0$, i.e., if there are more items to arrive, then we revise our estimate of n by doubling it, i.e., the new value of n is set as $n_1 := 2n_0$. We start **Alg** afresh on the next $\min\{n, n_1\} - n_0$ items. If $n > 2n_0$, then we set the new guess of n to be $n_2 := 2n_1 = 2^2n_0$ and start **Alg** afresh on the next $\min\{n, n_2\} - n_1$ number of items. We continue this process of doubling our estimate of n until all the items arrive. See Figure 1 for an illustration. The pseudocode is provided in Algorithm 2 in the Appendix.

We consider the following partition of the entire input into super-stages as follows: The first super-stage, Γ_0 , contains the first n_0 items. The second super-stage, Γ_1 , contains the next $n_1 - n_0$ items. In general, for $i > 0$, the $(i + 1)$ th super-stage, Γ_i , contains $\min\{n_i, n\} - n_{i-1}$ items which are given by $x_{n_{i-1}+1}, x_{n_{i-1}+2}, \dots, x_{\min\{n, n_i\}}$. So, essentially, **ImpAlg** can be thought of running **Alg** on each super-stage separately. The number of super-stages is given by $\kappa := \lceil \log(n/n_0) \rceil$. The last super-stage might not be *full*, i.e., ideally, it should contain $n/2$ items but it may not. An even worse case would be when the last stage of the last super-stage is not full, i.e., when it contains fewer than $|\Gamma_{\tau-1}|/2$ items where $\Gamma_{\tau-1}$ is the last super-stage. To see why this is bad, note that since we had assumed the value of n in **Alg**, it was possible to make sure that the last stage had exactly $n/2$ items. This is crucial because our analysis heavily relied on the fact that $|T_j| = \lceil \overline{T_j} \rceil$ for any stage T_j . This meant that the item set T_j fit almost perfectly in the proxy packing of $\overline{T_j}$. But if the last stage T_{m-1} contains far fewer items than $\overline{T_{m-1}}$, then we might be opening far too many proxy

bins than required (see the description of the last super-stage in Figure 1). Hence, we need a slight tweak in **Alg** in the way it packs a stage.

2.2.1 A Tweak to **Alg** in the Way in which a Stage is Packed

Recall that for any $j > 1$, we pack T_j as follows. Just before the stage T_j starts, we pack $\overline{T_j}$ using \mathcal{A}_α (the proxy packing). Instead of packing the entire set $\overline{T_j}$ at once, we do this in chunks. We divide the entire set $\overline{T_j}$ into $\eta := 1/\delta$ number of *equal* chunks. Let's denote these chunks by $\overline{T_j}^{(1)}, \overline{T_j}^{(2)}, \dots, \overline{T_j}^{(\eta)}$. Suppose each chunk contains c_j number of items. We first pack $\overline{T_j}^{(1)}$ using \mathcal{A}_α . Let this packing be denoted by $\mathcal{P}_j^{(1)}$. We pack the first c_j items of T_j by fitting them in the packing $\mathcal{P}_j^{(1)}$ just like we packed a stage in **Alg** by creating S -slots for small items and replacing a proxy item if we need to pack a large item. Then, we pack $\overline{T_j}^{(2)}$ using \mathcal{A}_α and fit the next c_j items of T_j in this packing just like before. We continue this process until all the items in T_j are packed. This way, if the size of T_j is very small compared to that of $\overline{T_j}$, then we only compute the proxy packing of only a few chunks and not of the entire set $\overline{T_j}$. On the other hand, if $|T_j|$ is significant when compared to $|\overline{T_j}|$, then we are anyway good since the number of chunks η is a constant. Intuitively, the optimal solution for $\overline{T_j}$ and the union of optimal solutions for η chunks $\overline{T_j}^{(1)}, \overline{T_j}^{(2)}, \dots, \overline{T_j}^{(\eta)}$ are close enough when η is a constant. See **PackStage** (Algorithm 3 in the Appendix) for details.

2.2.2 Analysis

The analyses of both **ImpAlg** and the tweak to **Alg** can be found in Appendix A.5. The intuition to why the tweak to **Alg** doesn't cause much problem has already been provided above. The analysis of **ImpAlg** is a bit complicated though. When n was known we had $O(1)$ stages. However, now we can have $\kappa = \lceil \log(n/n_0) \rceil$ number of super-stages. There can arise two problems:

- We can not analyze each super-stage individually and then sum up the performance guarantees, as we can not use union bound for a super-constant number of events. Moreover, we can't even use the analysis of **Alg** for the first few super-stages since they might only have a constant number of items. So, we consider the $\kappa_1 := \lceil \log(\delta^7 n) \rceil$ number of the initial super-stages at a time. We show that these initial super-stages contain only a small fraction of the entire input. Each of the final $(\kappa - \kappa_1)$ super-stages can be individually analyzed using the analysis of **Alg**.
- For each super-stage, we can have a constant number of S -bins (bins which contain only small items) with less occupancy. However, since the number of super-stages itself is a super-constant, this can result in a lot of wasted space. For this, we exploit the monotonicity of **NF** to ensure that we can pack small items from a super-stage into empty slots for small items from the previous stages.

See Appendix A.5.2 for the details.

3 Best-Fit under the Random-Order Model

In this section, we will prove Theorems 3 and 4.

3.1 When Item Sizes are Larger than $1/3$

First, let us recall upright matching and a related result that we will be using.

Upright Matching Problem. For a positive integer k , let S_k denote the set of all permutations of $[k]$. Consider a set of points P in the two-dimensional coordinate system. Suppose each item is marked as a *plus* point or a *minus* point. Let P^+ denote the set of plus points and let P^- denote the set of minus points. An edge exists between two points p^+, p^- iff $p^+ \in P^+, p^- \in P^-$ and iff p^+ lies above and to the right of p^- , i.e., both the coordinates of p^+ are greater than or equal to the corresponding coordinates of p^- . The objective is to find a maximum matching in this graph or, in other words, minimize the number of unmatched points. We denote the number of unmatched points by $U(P)$.

We will use the following variant of upright matching to prove the final result. Refer to [9] for the proof of the following lemma.

► **Lemma 12.** [9] *Let $k \in \mathbb{N}$ and let $\mathcal{A} = \{a_1, a_2, \dots, a_{2k}\}$ such that $a_i \geq a_{k+i}$ for all $i \in [k]$. Define a set of plus points $P^+ = \{(i, a_i) : i \in [k]\}$ and a set of minus points $P^- = \{(i, a_i) : k < i \leq 2k\}$. Suppose we randomly permute the x -coordinates of $P^+ \cup P^-$, i.e., for a uniform random permutation $\pi \in S_{2k}$, we redefine P^+ and P^- as $P^+ = \{(\pi(i), a_i) : i \in [k]\}$ and $P^- = \{(\pi(i), a_i) : k < i \leq 2k\}$. Let $P = P^+ \cup P^-$. Then, there exist universal constants $a, C, K > 0$ such that*

$$\mathbb{P} \left[U(P) \geq K\sqrt{k}(\log k)^{3/4} \right] \leq C \exp(-a(\log k)^{3/2}) \quad (16)$$

► **Remark 13.** In the above lemma, if we change the definitions of P^+, P^- to be $P_{\text{new}}^+ = \{(-\pi(i), a_i) : i \in [k]\}$, $P_{\text{new}}^- = \{(-\pi(i), a_i) : k < i \leq 2k\}$, the guarantee given by Equation (16) doesn't change since the new set $P_{\text{new}}^+ \cup P_{\text{new}}^-$ can be constructed by taking a mirror image of the original set $P^+ \cup P^-$ with respect to the y -axis. Since we consider random permutations, the probability of a set and its mirror image is the same.

With the above lemma and remark at hand, we now proceed to prove Theorem 3. Albers et al. [1] showed that the asymptotic random order ratio of the Best-Fit algorithm is at most 1.25 when all the item sizes are more than $1/3$. In this section, we improve it further and show that, Best-Fit for this special case under the random-order model is nearly optimal. We first show that the Modified Best-Fit algorithm [11] is nearly optimal and we analyze this using the above variant of stochastic upright matching. The Modified Best-Fit (MBF) algorithm is the same as BF except that it closes a bin if it receives an item of size less than $1/2$. Shor[44] showed that MBF *dominates* BF, i.e., for any instance I , $\text{BF}(I) \leq \text{MBF}(I)$. MBF can be easily reduced to upright matching as follows. Given an instance $I = \{x_1, \dots, x_n\}$, for any item $x_i \in I$, $x_i \in P^-$ if $x_i \leq 1/2$ with x -coordinate as $-i$ and y -coordinate as x_i , and $x_i \in P^+$ if $x_i > 1/2$ with x -coordinate as $-i$ and y -coordinate as $1 - x_i$. So, any item x_s of size $\leq 1/2$ can be matched with an item x_ℓ of size $> 1/2$ if and only if, x_ℓ arrives before x_s and the remaining space in the bin occupied by x_ℓ is more than the size of x_s .

Define an item x_i as a large item (L) if $x_i > 1/2$; otherwise, as a medium item (M) if $x_i \in (1/3, 1/2]$. We define a bin as LM -bin if it contains one large item and one medium item. We use the following lemma which was proved in [1] using the monotonicity property of BF when all item sizes are more than $1/3$.

► **Lemma 14.** [1] *Let I be any list that can be packed into $\text{Opt}(I)$ number of LM -bins. If Best-Fit has an AAR of α for I , then it has an AAR of α for any list of items larger than $1/3$ as well.*

Consider an input instance which has an optimal packing containing only LM -bins. Consider the number of bins opened by MBF for such instances. Each large item definitely opens a new bin, and a medium item opens a new bin if and only if it can not be placed

along with a large item, i.e., it is “unmatched”. So, the number of bins opened by MBF equals (number of large items+number of unmatched medium items). Now, we will prove our result.

► **Theorem 15.** *For any list I of items larger than $1/3$, the asymptotic random order ratio $RR_{BF}^\infty = 1$.*

Proof. From Lemma 14, it is enough to prove the theorem for any list I that can be packed in $\text{Opt}(I)$ LM -bins. So, we can assume that I has k large items and k medium items where $\text{Opt}(I) = k$. Now consider the packing of MBF for a randomly permuted list I_σ . We have, $\text{MBF}(I_\sigma) = (k + \text{number of unmatched medium items})$. Since the optimal packing has all the items matched, we can reduce the following case into the matching variant in Lemma 12: Let ℓ_i, m_i denote the sizes of the large item and the medium item respectively in the i^{th} bin of the optimal solution. For $i \in [k]$, we let $a_i = 1 - \ell_i$ and $a_{k+i} = m_i$ and let $\mathcal{A} = \{a_1, a_2, \dots, a_{2k}\}$. Note that the required condition in Lemma 12, i.e., $a_i \geq a_{k+i}$ is satisfied. The arrival order is randomly sampled from S_{2k} . So, we have

$$\text{MBF}(I_\sigma) = k + \frac{U(P)}{2} \leq k + K\sqrt{k}(\log k)^{3/4}$$

with probability of at least $1 - C \exp(-a(\log k)^{3/2})$ for some universal constants $a, C, K > 0$. Since MBF dominates BF we have

$$\mathbb{P} \left[\text{BF}(I_\sigma) \leq k + K\sqrt{k}(\log k)^{3/4} \right] \geq 1 - C \exp(-a(\log k)^{3/2}).$$

In case the high probability event does not occur, we can use the bound of $\text{BF}(I) \leq 1.7\text{Opt}(I) + 2$. Let $p := C \exp(-a(\log k)^{3/2})$. Then

$$\begin{aligned} \mathbb{E} [\text{BF}(I_\sigma)] &\leq p(1.7\mathbb{E}[k] + 2) + (1-p)(\mathbb{E}[k] + K\sqrt{\mathbb{E}[k]}(\log \mathbb{E}[k])^{3/4}) \\ &\leq \mathbb{E} [\text{Opt}(I)] + o(\mathbb{E} [\text{Opt}(I)]) \end{aligned} \quad (\text{since } p = o(1))$$

So, we get: $RR_{BF}^\infty = \limsup_{k \rightarrow \infty} \left(\sup_{I: \text{Opt}(I)=k} (\mathbb{E}[\text{BF}(I_\sigma)]/\text{Opt}(I)) \right) = 1$. This completes the proof. ◀

3.2 The 3-Partition Problem under Random-Order Model

In this section, we analyze the Best-Fit algorithm under the random-order model given that the item sizes lie in the range $(1/4, 1/2]$, and thus prove Theorem 4. We call an item *small* if its size lies in the range $(1/4, 1/3]$ and *medium* if its size lies in the range $(1/3, 1/2]$. Let I be the input list of items and let $n := |I|$. Recall that given σ , a uniform random permutation of $[n]$, I_σ denotes the list I permuted according to σ . We denote by $\text{Opt}(I_\sigma)$, the number of bins used in the optimal packing of I_σ and by $\text{BF}(I_\sigma)$, the number of bins used by Best-Fit to pack I_σ . Note that $\text{Opt}(I_\sigma) = \text{Opt}(I)$.

If there exists a set of three small items in I_σ such that they arrive as three consecutive items, we call that set to be an *S-triplet*. We call a bin to be a k -bin if it contains exactly k items, for $k \in \{1, 2, 3\}$. We sometimes refer to a bin by mentioning its contents more specifically as follows: An *MS*-bin is a 2-bin which contains a medium item and a small item. Similarly, an *SSS*-bin is a 3-bin which contains three small items. Likewise, we can define an *M*-bin, *S*-bin, *MM*-bin, *SS*-bin, *MMS*-bin, and *MSS*-bin.

Since the item sizes lie in $(1/4, 1/2]$, any bin in the optimal packing contains at most three items. For the same reason, in the packing by Best-Fit, every bin (with one possible

exception) contains at least two items. This trivially shows that the ECR of Best-Fit is at most $3/2$. To break the barrier of $3/2$, we use the following observations.

- Any 3-bin must contain a small item.
- So, if the optimal solution contains a lot of 3-bins, then it means that the input set contains a lot of small items.

We will prove that if there exist many small items in the input, then with high probability, in a random permutation of the input, there exist many disjoint S -triplets.

▷ **Claim 16.** Let m be the number of small items in the input set I , and let X_σ denote the maximum number of mutually disjoint S -triplets in I_σ . Suppose $m \geq cn$ where $c = 0.00033$, then the following statements hold true:

1. $\mathbb{E}[X_\sigma] \geq m^3/(3n^2) \geq c^3n/3$.
2. $X_\sigma \geq c^3n/3 - o(n)$ with high probability.

Then, we prove that Best-Fit packs at least one small item from an S -triplet in a 3-bin or in an SS -bin.

▷ **Claim 17.** Let $\{S_1, S_2, S_3\}$ be an S -triplet in I such that S_3 follows S_2 which in turn follows S_1 . Then, in the final packing of Best-Fit of I , at least one of S_1, S_2, S_3 is packed in a 3-bin or in an SS -bin. ◀

But the number of SS -bins in the final packing of Best-Fit can be at most one. So, we obtain that the number of 3-bins in the Best-Fit packing is significant. With these arguments, the proof of Theorem 4 follows. The detailed proofs of the above two claims and the final theorem is given in Appendix B.

4 Conclusion

We studied online bin packing under two stochastic settings, namely the i.i.d. model, and the random-order model. For the first setting, we devised a meta-algorithm which takes any offline algorithm \mathcal{A}_α with an AAR of α (where α can be any constant ≥ 1), and produces an online algorithm with an ECR of $(\alpha + \varepsilon)$. This shows that online bin packing under the i.i.d. model and offline bin packing are almost equivalent. Using any AFPTAS as \mathcal{A}_α results in an online algorithm with an ECR of $(1 + \varepsilon)$ for any constant $\varepsilon > 0$. An interesting question of theoretical importance is to find whether achieving an ECR of 1 is possible or not. Another related open question is if we can settle online bin packing under the random-order model as well.

Then, we studied the analysis of the well-known Best-Fit algorithm under the random-order model. First, we proved that the ECR of Best-Fit is equal to one if all the item sizes are greater than $1/3$. Then, we improved the analysis of the Best-Fit from 1.5 to ≈ 1.4941 , for the special case when the item sizes are in the range $(1/4, 1/2]$. An open question is to further improve this analysis since these instances are conjectured to be the hardest (offline) instances of bin packing. Another interesting problem would be to improve the lower bound on the ECR of Best-Fit in this model (which is currently 1.1 due to [2]).

A

 Omitted Details from Section 2

A.1 Omitted Proof of Lemma 7

The following claim follows directly from Theorem 2.1 in [42].

▷ **Claim 18.** Let I be a list of n items sampled independently from a distribution and let $I(1, t)$ denote the first t items. Then there exist constants $K_1, a_1 > 0$ such that

$$\mathbb{P} \left[\text{Opt}(I(1, t)) \geq \frac{t}{n} \text{Opt}(I) + K_1 \sqrt{n} (\log n)^{3/4} \right] \leq \exp \left(-a_1 (\log n)^{3/2} \right)$$

The next claim is a direct implication of the main result of [40].

▷ Claim 19. Let I be a list of n items sampled independently from a distribution. Then there exist constants $K_2, a_2 > 0$ such that

$$\mathbb{P} \left[\mathbb{E} [\text{Opt}(I)] \geq \text{Opt}(I) + K_2 \sqrt{n} (\log n)^{3/4} \right] \leq \exp \left(-a_2 (\log n)^{3/2} \right)$$

Combining both the claims, we obtain that there exist constants $K, a > 0$ such that

$$\mathbb{P} \left[\text{Opt}(I(1, t)) \geq \frac{t}{n} \mathbb{E} [\text{Opt}(I)] + K \sqrt{n} (\log n)^{3/4} \right] \leq \exp \left(-a (\log n)^{3/2} \right)$$

A.2 Omitted Proof of Lemma 8

We can assume that $\mathcal{W}(I)$ goes to infinity since we know that $\text{Opt}(I) \leq 2\mathcal{W}(I) + 1$. Let $K := \mathbb{E} [\mathcal{W}(I)]$ and $\mathcal{W}(x)$ be the weight of item x . Using Bernstein's inequality (Lemma 6),

$$\begin{aligned} & \mathbb{P} \left[\left| \sum_{x \in J} \mathcal{W}(x) - \sum_{x \in J} \mathbb{E} [\mathcal{W}(x)] \right| \geq K^{2/3} \right] \\ & \leq 2 \exp \left(-\frac{K^{4/3}}{2 \left(\sum_{x \in J} \mathbb{E} [\mathcal{W}(x)] + K^{2/3}/3 \right)} \right) \\ & \leq 2 \exp \left(-\frac{K^{4/3}}{2 \left(K + K^{2/3}/3 \right)} \right) \\ & \leq 2 \exp \left(-\frac{K^{4/3}}{2 \left(K + K/3 \right)} \right) \quad (\text{since } K \text{ goes to infinity, } K^{2/3} \leq K) \\ & \leq 2 \exp \left(-\frac{1}{3} K^{1/3} \right). \end{aligned}$$

Since $\sum_{x \in J} \mathcal{W}(x) = \mathcal{W}(J)$ and since $\mathbb{E} [\mathcal{W}(J)] = \frac{|J|}{n} \mathbb{E} [\mathcal{W}(I)]$, the lemma follows.

A.3 Omitted Proof of Lemma 9

We can assume that $\mathcal{W}(I)$ goes to infinity. Let $K := \mathbb{E} [\mathcal{W}(I)]$. For any item x , let L_x be the indicator random variable which denotes if the item x is a large item or not. Using Bernstein's inequality (Lemma 6),

$$\begin{aligned} & \mathbb{P} \left[\left| \sum_{x \in J} L_x - \sum_{x \in J} \mathbb{E} [L_x] \right| \geq K^{2/3} \right] \\ & \leq 2 \exp \left(-\frac{K^{4/3}}{2 \left(\sum_{x \in J} \mathbb{E} [L_x] + K^{2/3}/3 \right)} \right) \\ & = 2 \exp \left(-\frac{K^{4/3}}{2 \left(\mathbb{E} [|J_\ell|] + K^{2/3}/3 \right)} \right) \quad (\text{since } \sum_{x \in J} L_x = |J_\ell|) \\ & \leq 2 \exp \left(-\frac{K^{4/3}}{2 \left(K/\delta + K^{2/3}/3 \right)} \right) \quad (\text{since } K = \mathbb{E} [\mathcal{W}(I)] \geq \delta \mathbb{E} [|J_\ell|]) \\ & \leq 2 \exp \left(-\frac{\delta}{3} K^{1/3} \right). \end{aligned}$$

Since $\sum_{x \in J} L_x = |J_\ell|$ and since $\mathbb{E} [|J_\ell|] = \frac{|J|}{n} \mathbb{E} [|I_\ell|]$, the lemma follows.

A.4 Omitted Proof of Lemma 10

Let's denote the set of large items in $I(1, t)$ by $I_\ell(1, t)$ and denote the set of small items by $I_s(1, t)$. Consider any optimal packing of $I_\ell(1, t)$. Start packing $I_s(1, t)$ in the spaces left in the bins greedily using Next-Fit while opening new bins whenever necessary. This gives us a valid packing of $I(1, t)$.

If we don't open any new bins to pack $I_s(1, t)$, then by Lemma 7 for some constants $C_1, C_2 > 0$,

$$\begin{aligned}
\text{Opt}(I(1, t)) &\leq \text{Opt}(I_\ell(1, t)) \\
&\leq \frac{|I_\ell(1, t)|}{|I_\ell|} \mathbb{E}[\text{Opt}(I_\ell)] + C_1 \sqrt{\mathbb{E}[|I_\ell|]} (\log \mathbb{E}[|I_\ell|])^{3/4} && \text{(using Lemma 7)} \\
&\leq \frac{|I_\ell(1, t)|}{|I_\ell|} \mathbb{E}[\text{Opt}(I_\ell)] + \mathbb{E}[|I_\ell|]^{2/3} \\
&\leq \frac{\frac{t}{n} \mathbb{E}[|I_\ell|] + \mathbb{E}[\mathcal{W}(I)]^{2/3}}{|I_\ell|} \mathbb{E}[\text{Opt}(I_\ell)] + \mathbb{E}[|I_\ell|]^{2/3} && \text{(using Lemma 9)} \\
&\leq \frac{\frac{t}{n} (|I_\ell| + \mathbb{E}[\mathcal{W}(I)]^{2/3}) + \mathbb{E}[\mathcal{W}(I)]^{2/3}}{|I_\ell|} \mathbb{E}[\text{Opt}(I_\ell)] + \mathbb{E}[|I_\ell|]^{2/3} \\
&&& \text{(using Lemma 9)} \\
&\leq \frac{t}{n} \mathbb{E}[\text{Opt}(I)] + C_1 \mathbb{E}[\text{Opt}(I)]^{2/3} && \text{(using } \mathcal{W}(I) \geq \delta |I_\ell|)
\end{aligned}$$

with probability at least $1 - \exp(-a(\log \mathbb{E}[\text{Opt}(I)])^{1/3})$ for some constants $a, C_1 > 0$.

On the other hand, if we open new bins while packing $I_s(1, t)$, then after the final packing, every bin (except possibly one) is filled to a level of at least $1 - \delta$. Hence, in this case,

$$\begin{aligned}
\text{Opt}(I(1, t)) &\leq \frac{1}{1 - \delta} \mathcal{W}(I(1, t)) + 1 \\
&\leq (1 + 2\delta) \frac{t}{n} \mathbb{E}[\mathcal{W}(I)] + (1 + 2\delta) \mathbb{E}[\mathcal{W}(I)]^{2/3} + 1 \\
&\leq (1 + 2\delta) \frac{t}{n} \mathbb{E}[\text{Opt}(I)] + C_2 \mathbb{E}[\text{Opt}(I)]^{2/3} \\
&&& \text{(using } \text{Opt}(I) \geq \mathcal{W}(I) \text{ and } (1 - \delta)(1 + 2\delta) \geq 1 \text{ for } \delta < 1/2)
\end{aligned}$$

with probability at least $1 - \exp(-b \mathbb{E}[\text{Opt}(I)]^{1/3})$ for some constants $b, C_2 > 0$. This completes the proof.

A.5 Details of Section 2.2

A.5.1 Analysis of the Tweak in Alg to Pack a Stage

We will now analyze the number of bins used for a stage with the change of creating the proxy packing in chunks. Let η' be the final value of k in `PackStage` when it is run on T_j . The value of η' indicates the number of chunks of \overline{T}_j for which we have computed the packing by \mathcal{A}_α . For $p \in [\eta']$, let $T_j^{(p)}$ denote the set of items in T_j that we packed when $k = p$ in the run of `PackStage`, i.e., in the iteration when we consider the chunk $\overline{T}_j^{(p)}$. Note that for all $p \in [\eta' - 1]$, we have that $|T_j^{(p)}| = |\overline{T}_j^{(p)}|$. Let $A_j^{(p)}$ denote the number of bins used to pack $T_j^{(p)}$. Hence, from the analysis of `Alg`, specifically Equation (12), we obtain that with high

■ **Algorithm 2** ImpAlg: Improving Alg to get rid of the assumption on the knowledge of the number of items

```

1: Input:  $I_n(\mathcal{D}) = \{x_1, x_2, \dots, x_n\}$ .
2:  $n_{-1} \leftarrow 0; n_0 \leftarrow \frac{1}{\delta^3};$  for  $j \geq 1, n_j = 2n_{j-1}$ 
3:  $i \leftarrow 0$ 
4: while true do
5:   Run Alg( $x_{n_{i-1}+1}, x_{n_{i-1}+2}, \dots, x_{\min\{n_i, n\}}$ )
6:   if the input stream has ended then
7:     return the packing
8:   else
9:      $i \leftarrow i + 1$ 
10:  end if
11: end while

```

probability, for some constant C ,

$$\begin{aligned}
A_j^{(p)} &\leq \alpha(1 + 4\delta) \frac{|\overline{T}_j^{(p)}|}{n} \mathbb{E} [\text{Opt}(I)] + C \mathbb{E} [\text{Opt}(I)]^{2/3} + o(\text{Opt}(I)) \\
&= \alpha(1 + 4\delta) \frac{|T_j^{(p)}|}{n} \mathbb{E} [\text{Opt}(I)] + C \mathbb{E} [\text{Opt}(I)]^{2/3} + o(\text{Opt}(I))
\end{aligned} \tag{17}$$

For $p = \eta'$, it might be the case that $|T_j^{(p)}| < |\overline{T}_j^{(p)}|$. So, the following inequalities can be derived, which hold with high probability.

$$\begin{aligned}
A_j^{(\eta')} &\leq \alpha(1 + 4\delta) \frac{|\overline{T}_j^{(\eta')}|}{n} \mathbb{E} [\text{Opt}(I)] + C \mathbb{E} [\text{Opt}(I)]^{2/3} + o(\text{Opt}(I)) \\
&\leq \alpha(1 + 4\delta) \frac{|T_j^{(\eta')}| + |\overline{T}_j^{(\eta')}|}{n} \mathbb{E} [\text{Opt}(I)] + C \mathbb{E} [\text{Opt}(I)]^{2/3} + o(\text{Opt}(I)) \\
&\leq \alpha(1 + 4\delta) \frac{|T_j^{(\eta')}| + \frac{1}{\eta} |\overline{T}_j|}{n} \mathbb{E} [\text{Opt}(I)] + C \mathbb{E} [\text{Opt}(I)]^{2/3} + o(\text{Opt}(I)) \\
&\leq \alpha(1 + 4\delta) \frac{|T_j^{(\eta')}| + \frac{1}{\eta} |\overline{T}_j|}{n} \mathbb{E} [\text{Opt}(I)] + C \mathbb{E} [\text{Opt}(I)]^{2/3} + o(\text{Opt}(I)) \\
&\leq \alpha(1 + 4\delta) \left(\frac{|T_j^{(\eta')}|}{n} + \frac{1}{\eta} \right) \mathbb{E} [\text{Opt}(I)] + C \mathbb{E} [\text{Opt}(I)]^{2/3} + o(\text{Opt}(I))
\end{aligned} \tag{18}$$

The last inequality follows since $|\overline{T}_j| \leq n$. Summing Equation (17) over $p \in [\eta' - 1]$ and Equation (18), and observing that the number of chunks $\eta' \leq \eta$ is a constant, we get that with high probability, the number of bins used to pack the stage T_j , say A_j is bounded as follows.

$$\begin{aligned}
A_j &\leq \alpha(1 + 4\delta) \left(\frac{|T_j|}{n} + \frac{1}{\eta} \right) \mathbb{E} [\text{Opt}(I)] + \eta' C \mathbb{E} [\text{Opt}(I)]^{2/3} + o(\text{Opt}(I)) \\
&\leq \alpha(1 + 4\delta) \left(\frac{|T_j|}{n} + \delta \right) \mathbb{E} [\text{Opt}(I)] + \eta C \mathbb{E} [\text{Opt}(I)]^{2/3} + o(\text{Opt}(I))
\end{aligned} \tag{19}$$

But note that when $|T_j^{(\eta')}| = |\overline{T}_j^{(\eta')}|$, Equation (17) holds for $p = \eta'$ too. Then we obtain that

$$A_j \leq \alpha(1 + 4\delta) \frac{|T_j|}{n} \mathbb{E} [\text{Opt}(I)] + \eta C \mathbb{E} [\text{Opt}(I)]^{2/3} + o(\text{Opt}(I)) \quad (20)$$

Notice that Equation (20) and Equation (12) (which represents the analysis of a stage without chunking) are the same except for the constants in the lower order terms. Hence, for all the super-stages (except for the last), we can directly use the analysis of **Alg** as they are always full. For the last stage in the last super-stage, we need to use Equation (19). For the other stages in the last super-stage, we can use Equation (20) as they are always full.

From now on, we will assume that the way in which **Alg** packs a stage is tweaked in this manner.

A.5.2 Analysis of ImpAlg

Recall that the number of super-stages is given by $\kappa = \lceil \log(n/n_0) \rceil$ where n_0 was defined to be $1/\delta^3$. We will split the analysis into two parts. First, we will analyze the number of bins used by our algorithm in the first $\kappa_1 := \lceil \log(\delta^7 n) \rceil$ super-stages. Then, we will analyze the final $\kappa_2 := \kappa - \kappa_1$ super-stages considering one at a time. We call the first κ_1 super-stages as *initial super-stages* and the remaining κ_2 super-stages as *final super-stages*.

Analysis of the initial super-stages: The basic intuition of the analysis of our algorithm in the initial super-stages is as follows: Since only a small fraction of the entire input is present in these κ_1 super-stages, our algorithm uses only a small fraction of bins compared to the optimal packing of the entire input. So, we bound the number of large items and the weight of small items and thus bound the number of bins used.

► **Lemma 20.** *Let \mathcal{A} be an algorithm for online bin packing such that in the packing output by \mathcal{A} , every bin (except possibly a constant number of bins μ) which contains only small items has an occupancy of at least $(1 - \delta)$. Let I be a sequence of n i.i.d. items and let J be the prefix of I having size βn ($0 < \beta \leq 1$). Suppose \mathcal{A} works in a way such that it packs at most ν copies of any large item where ν is a constant³. Then the following inequality holds with high probability.*

$$\mathcal{A}(J) \leq \frac{2\beta\nu}{\delta(1-\delta)} \mathbb{E} [\text{Opt}(I)] + o(\mathbb{E} [\text{Opt}(I)])$$

Proof. Let J_ℓ, I_ℓ respectively denote the set of large items in J, I and let J_s, I_s respectively denote the set of small items in J, I . We prove the lemma considering two cases.

First, we consider the case when $|J_\ell| \leq \delta \text{Opt}(J)$. The number of bins in the packing of J by \mathcal{A} which contain at least one large item is upper bounded by $\nu |J_\ell|$. The number of bins

³ For example, **Alg** does this. Since it computes proxy packing several times, potentially, several copies of a large item can be packed. In the worst case, these copies may not get replaced, thus resulting in wasted space.

■ **Algorithm 3 PackStage:** Packing a stage T_j ($j \geq 1$, i.e., T_j is not the sampling stage)

```

1: Divide  $\overline{T}_j$  into chunks  $\overline{T}_j^{(1)}, \overline{T}_j^{(2)}, \dots, \overline{T}_j^{(\eta)}$  of equal size.
2:  $c_j \leftarrow$  size of each chunk.
3:  $k \leftarrow 1$  ▷ The number of chunks of  $\overline{T}_j$  processed
4: while stage  $T_j$  doesn't end do
5:    $D_j^{(k)} \leftarrow \overline{T}_j^{(k)}$ ;  $L(D_j^{(k)}) \leftarrow$  set of large items in  $D_j^{(k)}$ .
6:   Pack  $D_j^{(k)}$  by  $\mathcal{A}_\alpha$ ; denote this packing by  $\mathcal{P}_j^{(k)}$  ▷ The proxy packing
7:    $\mathcal{S}_j^{(k)} \leftarrow \phi$  ▷ the set of  $S$ -slots
8:   for bin  $B$  in  $\mathcal{P}_j^{(k)}$  do
9:     Remove the small items in  $B$ .
10:    Create an  $S$ -slot  $H$  of size equal to  $(1 - \text{weight of all the large items in } B)$ .
11:     $\mathcal{S}_j^{(k)} \leftarrow \mathcal{S}_j^{(k)} \cup H$ 
12:  end for
13:   $t \leftarrow 0$  ▷ Number of items arrived for the current chunk
14:  while an item  $x$  in  $T_j$  arrives and  $t \neq c_j$  do
15:    if  $x$  is large then
16:      if  $\exists d \in L(D_j^{(k)})$  such that  $d \geq x$  then
17:        Find smallest such  $d$ .
18:         $L(D_j^{(k)}) \leftarrow L(D_j^{(k)}) \setminus \{d\}$ .
19:        Pack  $x$  in place of  $d$  in the packing  $\mathcal{P}_j^{(k)}$ .
20:      else
21:        Open a new bin and pack  $x$  and close the bin.
22:      end if
23:    else
24:      Try packing  $x$  in  $\mathcal{S}_j^{(k)}$  using Next-Fit.
25:      if  $x$  couldn't be packed then
26:        Open a new bin  $B'$  with a single  $S$ -slot of unit capacity.
27:         $\mathcal{S}_j^{(k)} \leftarrow \mathcal{S}_j^{(k)} \cup B'$ .
28:        Pack  $x$  in  $B'$ .
29:      end if
30:    end if
31:     $t \leftarrow t + 1$ 
32:  end while
33:   $k \leftarrow k + 1$ 
34: end while

```

which contain only small items is upper bounded by $\mathcal{W}(J_s)/(1-\delta) + \mu$. Hence,

$$\begin{aligned}
\mathcal{A}(J) &\leq \nu |J_\ell| + \frac{\mathcal{W}(J_s)}{1-\delta} + \mu \\
&\leq \nu \delta \text{Opt}(J) + \frac{\text{Opt}(J)}{1-\delta} + \mu \\
&= \frac{1 + \nu(1-\delta)\delta}{1-\delta} \text{Opt}(J) + \mu \\
&\leq 2\nu(1+\delta)\text{Opt}(J) + \mu && \text{(since } 0 < \delta < 1/2 \text{ and } \nu \geq 1) \\
&\leq 2\beta\nu(1+\delta)(1+2\delta)\mathbb{E}[\text{Opt}(I)] + C_0\mathbb{E}[\text{Opt}(I)]^{2/3} && \text{w.h.p. for some constant } C_0 \\
& && \text{(using Lemma 10)} \\
&\leq \frac{2\beta\nu}{\delta(1-\delta)}\mathbb{E}[\text{Opt}(I)] + o(\mathbb{E}[\text{Opt}(I)]) \\
& && \text{(since } \delta < 1/2, 1+\delta < \frac{1}{1-\delta} \text{ and } 1+2\delta < \frac{1}{\delta})
\end{aligned}$$

Next, we consider the case when $|J_\ell| > \delta \text{Opt}(J)$. We will again bound the quantity $\nu |J_\ell| + \frac{\mathcal{W}(J_s)}{1-\delta} + \mu$. To bound $|J_\ell|$, we use Bernstein's inequality (Lemma 6). Let $X_1, X_2, \dots, X_{|J|}$ be random variables where X_i takes value 1 if the i^{th} item in J is large and 0 otherwise. Then, clearly, $|J_\ell| = \sum_{i=1}^{|J|} X_j$. Also, note that $\mathbb{E}[|J_\ell|] = \beta \mathbb{E}[|I_\ell|]$. Moreover, we can derive the following inequalities that hold with high probability.

$$\begin{aligned}
\mathbb{E}[|I_\ell|] &\geq \frac{1}{\beta} |J_\ell| - \frac{1}{\beta} \mathbb{E}[\mathcal{W}(I)]^{2/3} && \text{(using Lemma 9)} \\
&\geq \frac{\delta}{\beta} \text{Opt}(J) - \frac{1}{\beta} \mathbb{E}[\mathcal{W}(I)]^{2/3} \\
&\geq \frac{\delta}{\beta} \mathcal{W}(J) - \frac{1}{\beta} \mathbb{E}[\mathcal{W}(I)]^{2/3} \\
&\geq \frac{\delta}{\beta} \left(\beta \mathbb{E}[\mathcal{W}(I)] - \mathbb{E}[\mathcal{W}(I)]^{2/3} \right) - \frac{1}{\beta} \mathbb{E}[\mathcal{W}(I)]^{2/3} && \text{(using Lemma 8)} \\
&\geq \frac{\delta}{2} \mathbb{E}[\text{Opt}(I)] - o(\mathbb{E}[\text{Opt}(I)]) && \text{(since } \mathcal{W}(I) \leq \text{Opt}(I) \leq 2\mathcal{W}(I))
\end{aligned}$$

Hence, from now on, we will assume that there exists a constant $a_1 > 0$ such that

$$\mathbb{E}[|I_\ell|] \geq a_1 \mathbb{E}[\text{Opt}(I)] \quad (21)$$

Using Bernstein's inequality (Lemma 6),

$$\begin{aligned}
\mathbb{P}[|J_\ell| \geq 2\beta \mathbb{E}[|I_\ell|]] &= \mathbb{P}[|J_\ell| \geq \mathbb{E}[|J_\ell|] + \beta \mathbb{E}[|I_\ell|]] \\
&\leq 2 \exp\left(-\frac{\beta^2 \mathbb{E}[|I_\ell|]^2}{2\mathbb{E}[|J_\ell|] + \frac{2}{3}\beta \mathbb{E}[|I_\ell|]}\right) \\
&= 2 \exp\left(-\frac{3}{8}\beta \mathbb{E}[|I_\ell|]\right) \\
&\leq 2 \exp\left(-\frac{3}{8}\beta a_1 \cdot \mathbb{E}[\text{Opt}(I)]\right) && \text{(from Equation (21))}
\end{aligned}$$

Now to bound $\mathcal{W}(J_s)$, we will again use Bernstein's inequality on a new set of random variables $X_1, X_2, \dots, X_{|J|}$ where X_i equals the weight of the i^{th} item in J if it is small and 0

otherwise. Clearly, $\sum_{i=1}^{|J|} X_i = \mathcal{W}(J_s)$ and $\mathbb{E}[\mathcal{W}(J_s)] = \beta \mathbb{E}[\mathcal{W}(I_s)] \leq \beta \mathbb{E}[\mathcal{W}(I)]$. Thus,

$$\begin{aligned} \mathbb{P}[\mathcal{W}(J_s) \geq 2\beta \mathbb{E}[\mathcal{W}(I)]] &\leq \mathbb{P}[\mathcal{W}(J_s) \geq \mathbb{E}[\mathcal{W}(J_s)] + \beta \mathbb{E}[\mathcal{W}(I)]] \\ &\leq 2 \exp\left(\frac{-\beta^2 \mathbb{E}[\mathcal{W}(I)]^2}{2\mathbb{E}[\mathcal{W}(J_s)] + \frac{2}{3}\beta \mathbb{E}[\mathcal{W}(I)]}\right) \\ &= 2 \exp\left(\frac{-3\beta}{8} \mathbb{E}[\mathcal{W}(I)]\right) \\ &\leq 2 \exp\left(\frac{-3\beta \mathbb{E}[\text{Opt}(I)]}{16}\right) \quad (\text{since } 2\mathcal{W}(I) \geq \text{Opt}(I)) \end{aligned}$$

Thus, with high probability, we have that $|J_\ell| \leq 2\beta \mathbb{E}[|I_\ell|]$ and $\mathcal{W}(J_s) \leq 2\beta \mathbb{E}[\mathcal{W}(I)]$. Hence,

$$\begin{aligned} \mathcal{A}(J) &\leq \nu |J_\ell| + \frac{\mathcal{W}(J_s)}{1-\delta} + \mu \\ &\leq 2\nu\beta \mathbb{E}[|I_\ell|] + \frac{2\beta \mathbb{E}[\mathcal{W}(I)]}{1-\delta} + \mu \\ &\leq \frac{2\nu\beta}{\delta} \mathbb{E}[\text{Opt}(I)] + \frac{2\beta \mathbb{E}[\text{Opt}(I)]}{1-\delta} + \mu \\ &= \frac{2\nu\beta}{\delta(1-\delta)} \mathbb{E}[\text{Opt}(I)] + o(\mathbb{E}[\text{Opt}(I)]) \end{aligned}$$

This completes the proof. \blacktriangleleft

With the help of the above lemma, we proceed to analyze **ImpAlg** for the initial (first κ_1) super-stages. Note that the number of items in the initial super-stages is given by $2^{\kappa_1-1} n_0 \leq (\delta^7 n_0) n = \delta^4 n$. Since **Alg** satisfies the properties of \mathcal{A} in Lemma 20 and **ImpAlg** just applies **Alg** multiple times, we can use Lemma 20 to analyze **ImpAlg**.

There is one difficulty though. Let's call a bin which contains only small items to be an S -bin. Although in a super-stage the number of S -bins not filled up to a level of at least $(1-\delta)$ is a constant, the number of initial super-stages itself is not a constant. We can work around this problem by continuing NF to pack the small items in the S -slots created during the previous stages and the previous super-stages as well. In other words, instead of packing the small items of a stage in S -slots created only during that stage, we keep a global set of S -slots and pack the small items using NF. We now have to show that our algorithm doesn't increase the number of bins with this change. Since the way in which the large items are packed hasn't changed, the number of bins that contain large items does not change. Since NF is monotone (even with varying bin sizes, [37]), the number of bins containing only the small items will either decrease or stays the same.

Hence, using Lemma 20 with $\nu = 1/\delta^2$ (since each super-stage contains $1/\delta^2$ stages and so, each large item in this super-stage can be packed at most $1/\delta^2$ times), we obtain that with high probability,

$$\begin{aligned} \text{Alg}(\Gamma_0) + \text{Alg}(\Gamma_1) + \dots + \text{Alg}(\Gamma_{\kappa_1-1}) &\leq \frac{2(1/\delta^2)\delta^4}{\delta(1-\delta)} \mathbb{E}[\text{Opt}(I)] + o(\text{Opt}(I)) \\ &\leq 4\delta \mathbb{E}[\text{Opt}(I)] + o(\text{Opt}(I)) \end{aligned} \quad (22)$$

Analysis of the final super-stages: For this part, the important thing to note is that $\kappa_2 \leq \lceil \log(1/(\delta^7 n_0)) \rceil$ is a constant. Moreover, since the number of items in the initial super-stages is at least $\delta^4 n/2$, each of the final super-stages has at least $\delta^4 n/2$ items (which tends to infinity in the limiting case). Thus, we can use the analysis of **Alg** for each of these

final super-stages. As mentioned, since the last super-stage might not be full, we analyze the last super-stage differently. All the other super-stages are full. So, we can directly use the analysis of **Alg**. For all $\kappa_1 \leq i < \kappa - 1$, from the analysis of **Alg** (Equation (14)), we have that with high probability

$$\mathbf{Alg}(\Gamma_i) \leq \alpha(1 + 8\delta)\mathbb{E}[\text{Opt}(\Gamma_i)] + C\mathbb{E}[\text{Opt}(\Gamma_i)]^{2/3} + o(\text{Opt}(\Gamma_i))$$

for some constant C .

Now, to bound $\text{Opt}(\Gamma_i)$ in terms of $\text{Opt}(I)$, we can use Lemma 10. Thus, the above inequality transforms into

$$\begin{aligned} \mathbf{Alg}(\Gamma_i) &\leq \alpha(1 + 8\delta)(1 + 2\delta)\frac{|\Gamma_i|}{n}\mathbb{E}[\text{Opt}(I)] + C_1\mathbb{E}[\text{Opt}(\Gamma_i)]^{2/3} + o(\text{Opt}(\Gamma_i)) \\ &\leq \alpha(1 + 8\delta)(1 + 2\delta)\frac{|\Gamma_i|}{n}\mathbb{E}[\text{Opt}(I)] + C_1\mathbb{E}[\text{Opt}(I)]^{2/3} + o(\text{Opt}(I)) \end{aligned}$$

for some constant C_1 . Summing over all i ($\kappa_1 \leq i < \kappa - 1$), and observing that $\kappa - \kappa_1$ is a constant, we obtain that with high probability,

$$\begin{aligned} &\mathbf{Alg}(\Gamma_{\kappa_1}) + \mathbf{Alg}(\Gamma_{\kappa_1+1}) + \cdots + \mathbf{Alg}(\Gamma_{\kappa-2}) \\ &\leq \alpha(1 + 8\delta)(1 + 2\delta)\sum_{i=\kappa_1}^{\kappa-2}\frac{|\Gamma_i|}{n}\mathbb{E}[\text{Opt}(I)] + C_2\mathbb{E}[\text{Opt}(I)]^{2/3} + o(\text{Opt}(I)) \\ &\leq \alpha(1 + 26\delta)\sum_{i=\kappa_1}^{\kappa-2}\frac{|\Gamma_i|}{n}\mathbb{E}[\text{Opt}(I)] + C_2\mathbb{E}[\text{Opt}(I)]^{2/3} + o(\text{Opt}(I)) \end{aligned} \quad (23)$$

for some constant C_2 .

Now consider the last super-stage $\Gamma_{\kappa-1}$. If $|\Gamma_{\kappa-1}|$ is exactly equal to $n_{\kappa-1} - n_{\kappa-2}$, then we can obtain the same bound as Equation (23). However, this might not be the case. So, we consider two cases. If we don't go beyond the sampling stage of the last-stage, i.e., if $|\Gamma_{\kappa-1}| \leq \delta^2(n_{\kappa-1} - n_{\kappa-2})$, then using Lemma 20 with $\nu = 1$ (since we just use NF), we obtain that with high probability,

$$\begin{aligned} \mathbf{Alg}(\Gamma_{\kappa-1}) &\leq \frac{2\delta^2(n_{\kappa-1} - n_{\kappa-2})}{n\delta(1 - \delta)}\mathbb{E}[\text{Opt}(I)] + o(\mathbb{E}[\text{Opt}(I)]) \\ &\leq 4\delta\mathbb{E}[\text{Opt}(I)] + o(\mathbb{E}[\text{Opt}(I)]) \end{aligned} \quad (24)$$

where the last inequality follows from the facts that $\delta \leq 1/2$ and $n \geq n_{\kappa-1} - n_{\kappa-2}$. On the other hand, if $|\Gamma_{\kappa-1}| > \delta^2 2^{k-1} n_0$, then note that when **Alg** was run on $\Gamma_{\kappa-1}$, it must have completed the sampling stage (since the size of the sampling stage is only $\delta^2(n_{\kappa-1} - n_{\kappa-2})$) and proceeded into the remaining stages.

Let's denote the number of bins used in the sampling stage of the last super-stage by $A_{\kappa-1}^{(\text{samp})}$ and the bins used in the remaining stages by $A_{\kappa-1}^{(\text{rem})}$. Using Lemma 20 with $\nu = 1$, with high probability, we can bound $A_{\kappa-1}^{(\text{samp})}$:

$$\begin{aligned} A_{\kappa-1}^{(\text{samp})} &\leq \frac{2\delta^2(n_{\kappa-1} - n_{\kappa-2})}{n\delta(1 - \delta)}\mathbb{E}[\text{Opt}(I)] + o(\mathbb{E}[\text{Opt}(I)]) \\ &\leq 4\delta\mathbb{E}[\text{Opt}(I)] + o(\mathbb{E}[\text{Opt}(I)]) \end{aligned}$$

Let the number of stages in the last super-stage be τ . Let $\Gamma_{\kappa-1}^{(j)}$ denote the set of items in the j^{th} stage of the super-stage $\Gamma_{\kappa-1}$. For each $j \in [\tau - 1]$, we can use Equation (20) to

bound the number of bins used for packing $\Gamma_{\kappa-1}^{(j)}$. For $\Gamma_{\kappa-1}^{(\tau)}$, we can use Equation (19) to bound the number of bins. Thus, with high probability, for some constant C_3 , we obtain that

$$\begin{aligned} A_{\kappa-1}^{(\text{rem})} &\leq \alpha(1+4\delta) \left(\sum_{j=1}^{\tau-1} \frac{|\Gamma_{\kappa-1}^{(j)}|}{n} + \left(\frac{|\Gamma_{\kappa-1}^{(\tau)}|}{n} + \delta \right) \right) \mathbb{E} [\text{Opt}(I)] \\ &\quad + C_3 \mathbb{E} [\text{Opt}(I)]^{2/3} + o(\text{Opt}(I)) \\ &\leq \alpha(1+4\delta) \left(\frac{|\Gamma_{\kappa-1}|}{n} + \delta \right) \mathbb{E} [\text{Opt}(I)] + C_3 \mathbb{E} [\text{Opt}(I)]^{2/3} + o(\text{Opt}(I)) \end{aligned}$$

Hence, the total number of bins used by **ImpAlg** for the last super-stage $A_{\kappa-1}^{(\text{samp})} + A_{\kappa-1}^{(\text{rem})}$ can be bounded as

$$\begin{aligned} \text{Alg}(\Gamma_{\kappa-1}) &\leq \alpha(1+4\delta) \left(\frac{|\Gamma_{\kappa-1}|}{n} + 5\delta \right) \mathbb{E} [\text{Opt}(I)] + C_3 \mathbb{E} [\text{Opt}(I)]^{2/3} + o(\text{Opt}(I)) \\ &\leq \alpha(1+26\delta) \left(\frac{|\Gamma_{\kappa-1}|}{n} + 5\delta \right) \mathbb{E} [\text{Opt}(I)] + C_3 \mathbb{E} [\text{Opt}(I)]^{2/3} + o(\text{Opt}(I)) \quad (25) \end{aligned}$$

It can be seen that among Equation (25) and Equation (24), the former (i.e., when we complete the sampling stage of the last super-stage) represents the worst case scenario.

Summing Equations (22), (23), and (25), we obtain that with high probability, for some constant C_4 ,

$$\begin{aligned} \text{ImpAlg}(I) &= \sum_{j=0}^{\kappa_1-1} \text{Alg}(\Gamma_j) + \sum_{j=\kappa_1}^{\kappa-2} \text{Alg}(\Gamma_j) + \text{Alg}(\Gamma_{\kappa-1}) \\ &\leq \left(4\delta + \alpha(1+26\delta) \left(\sum_{i=\kappa_1}^{\kappa-2} \frac{|\Gamma_i|}{n} + \frac{|\Gamma_{\kappa-1}|}{n} + 5\delta \right) \right) \mathbb{E} [\text{Opt}(I)] \\ &\quad + C_4 \mathbb{E} [\text{Opt}(I)]^{2/3} + o(\text{Opt}(I)) \\ &\leq (4\delta + \alpha(1+26\delta)(1+5\delta)) \mathbb{E} [\text{Opt}(I)] \\ &\quad + C_4 \mathbb{E} [\text{Opt}(I)]^{2/3} + o(\text{Opt}(I)) \\ &\leq \alpha(1+165\delta) \mathbb{E} [\text{Opt}(I)] \\ &\quad + C_4 \mathbb{E} [\text{Opt}(I)]^{2/3} + o(\text{Opt}(I)) \quad (26) \end{aligned}$$

Equation (26) holds with high probability, say $p = 1 - o(1)$. In the scenario where the low probability event occurs, we can bound the number of bins used by **ImpAlg** using Lemma 20 with $\beta = 1$ and $\nu = 1/\delta^2$:

$$\text{ImpAlg}(I) \leq \frac{2(1/\delta^2)}{\delta(1-\delta)} \mathbb{E} [\text{Opt}(I)] + o(\mathbb{E} [\text{Opt}(I)])$$

Let E be the event when Equation (26) holds. Then

$$\begin{aligned} \mathbb{E} [\text{ImpAlg}(I)] &= \mathbb{E} [\text{ImpAlg}(I)|E] \mathbb{P} [E] + \mathbb{E} [\text{ImpAlg}(I)|\bar{E}] \mathbb{P} [\bar{E}] \\ &\leq \left((\alpha(1+165\delta)) \mathbb{E} [\text{Opt}(I)] + o(\mathbb{E} [\text{Opt}(I)]) \right) (1 - o(1)) \\ &\quad + \left(\frac{2}{\delta^3(1-\delta)} \mathbb{E} [\text{Opt}(I)] + 1 \right) o(1) \\ &= (\alpha(1+165\delta)) \mathbb{E} [\text{Opt}(I)] + o(\mathbb{E} [\text{Opt}(I)]) \end{aligned}$$

Choosing $\delta = \frac{\varepsilon}{165\alpha}$ ensures that the competitive ratio of **ImpAlg** is $\alpha + \varepsilon$.

B

 Details of Section 3.2

Proof of Claim 16. One can construct a random permutation of the input list I by first placing the small items in a random order and then inserting the remaining items among the small items randomly.

After placing the small items, we have $m + 1$ gaps to place the remaining items as shown below in the form of empty squares.

$$\square \underbrace{S \square S \square S}_{\text{Triplet } T_1} \square \underbrace{S \square S \square S}_{\text{Triplet } T_2} \square \underbrace{S \square S \square S}_{\text{Triplet } T_3} \cdots \underbrace{S \square S \square S}_{\text{Triplet } T_{m/3}} \square$$

As shown above, we name the S -triplets as $T_1, T_2, \dots, T_{m/3}$ (Strictly speaking, the number of S -triplets should be $\lfloor m/3 \rfloor$, but we relax this since we are only interested in the asymptotic case and $m \geq cn$). Let us start inserting the non-small items into these empty squares. Consider any S -triplet T_i . The probability that T_i continues to be an S -triplet after inserting the first non-small item is $(m-1)/(m+1)$. The first non-small item thus occupies one of the squares, but in this process, it creates two new squares on either side of itself, thereby increasing the net number of squares by one. Hence, the probability that T_i continues to be an S -triplet after inserting the second non-small item (given it remains to be one after inserting the first non-small item) is $m/(m+2)$. We continue this process of inserting the non-small items and after they all have been inserted, let $Y_\sigma^{(i)}$ be the indicator random variable denoting whether T_i is consecutive or not. Then

$$\mathbb{E} \left[Y_\sigma^{(i)} \right] = \frac{m-1}{m+1} \frac{m}{m+2} \cdots \frac{n-2}{n} = \frac{m(m-1)}{n(n-1)}.$$

Let $Y_\sigma = Y_\sigma^{(1)} + Y_\sigma^{(2)} + \cdots + Y_\sigma^{(m/3)}$, by linearity of expectations,

$$\lim_{n, m \rightarrow \infty} \mathbb{E} [Y_\sigma] = \lim_{n, m \rightarrow \infty} \frac{m}{3} \frac{m(m-1)}{n(n-1)} \approx \frac{m^3}{3n^2} \geq \frac{c^3 n}{3}.$$

Since $X_\sigma \geq Y_\sigma$, the first part of the claim follows.

To prove the second part of the claim, we will compute $\text{Var} [Y_\sigma]$ and use Chebyshev's inequality. For any i ,

$$\begin{aligned} \text{Var} \left[Y_\sigma^{(i)} \right] &= \mathbb{E} \left[Y_\sigma^{(i)} \right] - \mathbb{E} \left[Y_\sigma^{(i)} \right]^2 \\ &= \frac{m(m-1)}{n(n-1)} - \frac{m^2(m-1)^2}{n^2(n-1)^2} \\ &= \frac{m(m-1)(n-m)(n+m-1)}{n^2(n-1)^2} \\ &\leq 2 \end{aligned} \tag{27}$$

Now, consider any two S -triplets T_j, T_k . The probability that both T_j and T_k remain to be S -triplets after inserting the first non-small item is $(m-3)/(m+1)$. Continuing in this manner, after all the non-small items have been inserted,

$$\mathbb{E} \left[Y_\sigma^{(j)} Y_\sigma^{(k)} \right] = \mathbb{P} \left[Y_\sigma^{(j)} = 1 \wedge Y_\sigma^{(k)} = 1 \right] = \frac{m-3}{m+1} \frac{m}{m+2} \cdots \frac{n-4}{n} = \frac{m(m-1)(m-2)(m-3)}{n(n-1)(n-2)(n-3)}$$

The covariance of $Y_\sigma^{(j)}, Y_\sigma^{(k)}$ is given by

$$\begin{aligned}
 \text{Cov} [Y_\sigma^{(j)}, Y_\sigma^{(k)}] &= \mathbb{E} [Y_\sigma^{(j)} Y_\sigma^{(k)}] - \mathbb{E} [Y_\sigma^{(j)}] \mathbb{E} [Y_\sigma^{(k)}] \\
 &= \frac{m(m-1)(m-2)(m-3)}{n(n-1)(n-2)(n-3)} - \frac{m^2(m-1)^2}{n^2(n-1)^2} \\
 &= \frac{m(n-m)(m-1)(4nm-6m-6n+6)}{n^2(n-1)^2(n-2)(n-3)} \\
 &\leq \frac{4n^3(n-1)^2}{n^2(n-1)^2(n-2)(n-3)} \\
 &= \frac{4n}{(n-2)(n-3)} \\
 &\leq \frac{6}{n}
 \end{aligned} \tag{28}$$

Combining all these, the variance of Y_σ can be calculated as follows

$$\begin{aligned}
 \text{Var} [Y_\sigma] &= \sum_{i=1}^{m/3} \text{Var} [Y_\sigma^{(i)}] + 2 \sum_{1 \leq j < k \leq m/3} \text{Cov} [Y_\sigma^{(j)}, Y_\sigma^{(k)}] \\
 &\leq \frac{2m}{3} + \frac{m}{3} \left(\frac{m}{3} - 1 \right) \frac{6}{n} \quad (\text{from Equations (27) and (28)}) \\
 &\leq 2n
 \end{aligned}$$

Now using Chebyshev's inequality,

$$\begin{aligned}
 \mathbb{P} [Y_\sigma \leq \mathbb{E} [Y_\sigma] - (\mathbb{E} [Y_\sigma])^{2/3}] &\leq \mathbb{P} [|Y_\sigma - \mathbb{E} [Y_\sigma]| \geq (\mathbb{E} [Y_\sigma])^{2/3}] \\
 &\leq \frac{\text{Var} [Y_\sigma]}{(\mathbb{E} [Y_\sigma])^{4/3}} \\
 &\leq \frac{2n}{\frac{c^4}{3^{4/3}} n^{4/3}} \\
 &= O \left(\frac{1}{n^{1/3}} \right), \text{ as } c \text{ is a constant.}
 \end{aligned}$$

Since X_σ is the maximum number of S -triplets, $X_\sigma \geq Y_\sigma \geq c^3 n/3 - o(n)$ with high probability. \blacktriangleleft

Proof of Claim 17. There are three cases we need to consider.

- If S_1 is going to be packed in a 2-bin. Then after packing S_1 , this bin becomes a 3-bin and hence the claim holds.
- Suppose S_1 is going to be packed in a 1-bin B . Then just before the arrival of S_1 , B must have been the only 1-bin and hence, after packing S_1 , each bin is either a 2-bin or a 3-bin.
 - Now, if one of S_2, S_3 is packed into a 2-bin, then the bin becomes a 3-bin and the claim follows.
 - Otherwise, both S_2, S_3 are packed into a single new SS -bin and hence the claim follows.
- Suppose S_1 is packed in a new bin. Then just prior to the arrival of S_2 , every bin is either a 2-bin or 3-bin except the bin containing S_1 . Thus, S_2 is either packed in a 2-bin (thus becoming a 3-bin) or packed in the bin containing S_1 , resulting in an SS -bin. \blacktriangleleft

Now we prove Theorem 4.

Proof of Theorem 4. Consider the final Best-Fit packing of I_σ . Let X_3 be the number of 3-bins. The remaining $(n - 3X_3)$ items are packed in 2-bins and at most one 1-bin. Therefore,

$$\text{BF}(I_\sigma) \leq X_3 + \frac{n - 3X_3}{2} + 1 = \frac{n - X_3}{2} + 1 \leq \frac{3}{2} \left(1 - \frac{X_3}{n}\right) \text{Opt}(I_\sigma) + 1 \quad (29)$$

The last inequality follows from the fact that any bin in the optimal solution can accommodate at most three items. Let $z_1 (\leq 1)$, z_2 and z_3 be the number of 1-bins, 2-bins and 3-bins in the optimal packing of I_σ , respectively. Then, $\text{Opt}(I_\sigma) = z_1 + z_2 + z_3$ and $n = z_1 + 2z_2 + 3z_3$. Note that any two items can fit in a bin. Therefore,

$$\text{BF}(I_\sigma) \leq \frac{n + 1}{2} = \frac{z_1 + 2z_2 + 3z_3 + 1}{2} \leq \frac{3\text{Opt}(I_\sigma) - z_2 - 2z_1 + 1}{2} \leq \left(\frac{3}{2} - \frac{\mu}{2}\right) \text{Opt}(I_\sigma) + 1 \quad (30)$$

where $\mu := z_2/\text{Opt}(I_\sigma)$ is the fraction of 2-bins in the optimal solution.

When μ is close to one (say $\mu > 0.999$), we already obtain a competitive ratio very close to 1 due to the above inequality. When $\mu \leq 0.999$, then m , the number of small items in the input list is at least $0.00033n$. This is because z_3 , the number of 3-bins in the optimal solution, is at least $0.001\text{Opt}(I_\sigma) - 1 \geq 0.001(n/3) - 1 \geq 0.00033n$ and any 3-bin must contain at least one small item.

Hence, assuming $\mu \leq 0.999$, let us analyze the Best-Fit packing of I_σ in a different way. Let n_s be the number of small items. Since a 3-bin contains at least one small item, we know that, $n_s \geq z_3 \geq (1 - \mu)\text{Opt}(I_\sigma) - z_1$. Let X_σ be the random variable which denotes the maximum number of S -triplets in the input sequence. By Claim 16,

$$X_\sigma \geq \frac{((1 - \mu)\text{Opt}(I_\sigma) - z_1)^3}{3n^2} - o(n) \approx \frac{(1 - \mu)^3 \text{Opt}(I_\sigma)^3}{3n^2} - o(n) \text{ w.h.p., as } z_1 \leq 1.$$

In the Best-Fit solution, the number of SS -bins can at most be one. Hence, by Claim 17,

$$X_3 \geq \frac{X_\sigma}{3} - 1 \geq \frac{(1 - \mu)^3 \text{Opt}(I_\sigma)^3}{9n^2} - o(n) \geq \frac{(1 - \mu)^3 n}{243} - o(n) \text{ w.h.p.}$$

The last inequality follows from the fact that $\text{Opt}(I_\sigma) \geq n/3$. Using Equation (29), we get,

$$\begin{aligned} \text{BF}(I_\sigma) &\leq \frac{3}{2} \left(1 + \frac{o(n)}{n} - \frac{(1 - \mu)^3}{243}\right) \text{Opt}(I_\sigma) + 1 \\ &\leq \frac{3}{2} \left(1 - \frac{(1 - \mu)^3}{243}\right) \text{Opt}(I_\sigma) + o(\text{Opt}(I_\sigma)) \text{ w.h.p.} \end{aligned} \quad (31)$$

Equations (30) and (31) are the result of two different ways of analyzing the same algorithm. Hence, the expected competitive ratio is given by $\min\left\{\frac{3}{2} - \frac{\mu}{2}, \frac{3}{2} - \frac{(1 - \mu)^3}{162}\right\}$. When both the above quantities are equal, we obtain the worst-case competitive ratio. This happens when $81\mu = (1 - \mu)^3$, i.e., $\mu \approx 0.01191$; the approximation ratio, in this case, is roughly 1.494045.

We just proved that with high probability, say $p = 1 - o(1)$, $\text{BF}(I) \leq 1.494045\text{Opt}(I) + o(\text{Opt}(I))$. The fact that $\text{BF}(I) \leq 1.7\text{Opt}(I) + 2$ always holds due to [28]. Combining both these, $\mathbb{E}[\text{BF}(I)] \leq p(1.494045\mathbb{E}[\text{Opt}(I)] + o(\mathbb{E}[\text{Opt}(I)])) + (1 - p)(1.7\mathbb{E}[\text{Opt}(I)] + 2)$. Thus we obtain that $\mathbb{E}[\text{Opt}(I)] \leq 1.494045\mathbb{E}[\text{Opt}(I)] + o(\mathbb{E}[\text{Opt}(I)])$.

This completes the proof of Theorem 4. \blacktriangleleft

C Multidimensional Online Vector Packing Problem under i.i.d. model

In this section, we design an algorithm for d -dimensional online vector packing problem (d-OVP) where d is a positive integer constant. In this entire section, we abbreviate a tuple with d entries as just *tuple*. A tuple Y is represented as $(Y^{(1)}, Y^{(2)}, \dots, Y^{(d)})$. We define Y^{\max} to be $\max\{Y^{(1)}, Y^{(2)}, \dots, Y^{(d)}\}$. In d-OVP, the input set I consists of n tuples X_1, X_2, \dots, X_n which arrive in online fashion; we assume that n is known beforehand. Each $X_i^{(j)}$ is sampled independently from a distribution $\mathcal{D}^{(j)}$. The objective is to partition the n tuples into a minimum number of bins such that for any bin B and any $j \in [d]$, the sum of all the j^{th} entries of all the tuples in B does not exceed one. Formally, we require that for any bin B and any $j \in [d]$, $\sum_{x \in B} x^{(j)} \leq 1$.

C.1 Algorithm

Given an offline α -asymptotic approximation algorithm \mathcal{A}_α for bin packing, we obtain a $(d\alpha + \varepsilon)$ -competitive algorithm for d-OVP as follows: For every input tuple X_i , we round each $X_i^{(j)}, j \in [d]$ to X_i^{\max} . After rounding, since all the tuples have same values in each of the d entries, we can treat each tuple X_i as an one-dimensional item of size X_i^{\max} .

It is easy to see that each X_i^{\max} is independently sampled from the same distribution: Let $F^{(j)}$ be the cumulative distribution function (CDF) of $\mathcal{D}^{(j)}$. Then the CDF, F , of X_i^{\max} (for any $i \in [n]$) is given by

$$\begin{aligned} F(y) = \mathbb{P}[X_i^{\max} \leq y] &= \prod_{j=1}^d \mathbb{P}[X_i^{(j)} \leq y] && \text{(By independence of } X_i^{(j)}\text{s)} \\ &= \prod_{j=1}^d F^{(j)}(y) \end{aligned}$$

Hence, the problem at hand reduces to solving an online bin packing problem where items are independently sampled from a distribution whose CDF is given by the function $\prod_{i=1}^d F^{(j)}$. So, we can use the algorithm from Section 2.

C.2 Analysis

Let I denote the vector packing input instance and let \bar{I} denote the rounded up one-dimensional bin packing instance.

► **Lemma 21.** *Let $\text{Opt}_v(I)$ denote the optimal number of bins used to pack I . Then $\text{Opt}(\bar{I}) \leq d\text{Opt}_v(I)$.*

Proof. Consider any optimal packing of I . We show how to construct a feasible packing of \bar{I} starting from the optimal packing of I . Consider any bin in the optimal packing of I and let B denote the set of tuples packed inside it. Let \bar{B} denote the rounded-up instance of B . Also, for $j \in [d]$, let $B^{(j)}$ denote the set of tuples whose j^{th} dimension has the largest weight, i.e.,

$$B^{(j)} = \left\{ Y \in B : Y^{(j)} = Y^{\max} \right\}$$

If any tuple belongs to $B^{(j)}$ as well as $B^{(k)}$ for some $j \neq k$, we break these ties arbitrarily and assign it to one of $B^{(j)}, B^{(k)}$. For $j \in [d]$, let $\bar{B}^{(j)}$ denote the rounded instance of $B^{(j)}$.

We can pack \overline{B} in at most d bins as follows: For any $j \in [d]$, we know that

$$\sum_{Y \in B^{(j)}} Y^{(j)} \leq 1$$

and since for all $Y \in B^{(j)}$, $Y^{\max} = Y^{(j)}$, it follows that

$$\sum_{Z \in \overline{B^{(j)}}} Z \leq 1$$

Hence, we can pack every $\overline{B^{(j)}}$ in one bin and the lemma follows. \blacktriangleleft

Now we are ready to prove our main theorem of this section.

► Theorem 22. *For any $\varepsilon > 0$ and a given polynomial-time α -approximation algorithm for online bin packing, we can obtain a polynomial-time algorithm for d -OVP with an asymptotic approximation ratio of $(\alpha d + \varepsilon d)$.*

Proof. Let us denote our present algorithm by Alg_v . Then we get:

$$\text{Alg}_v(I) = \text{Alg}(\overline{I}) \tag{32}$$

$$\leq (\alpha + \varepsilon)\text{Opt}(\overline{I}) + o(\text{Opt}(\overline{I})) \tag{33}$$

$$\leq (\alpha d + \varepsilon d)\text{Opt}_v(I) + o(\text{Opt}_v(I)). \tag{34}$$

Here, Equation (32) follows from the property of Alg_v , (33) follows from the results of Section 2, and (34) follows from Lemma 21. This concludes the proof. \blacktriangleleft
