arXiv:2205.07061v1 [cs.IT] 14 May 2022

Abstract—We are assisting at a growing interest in the development of learning architectures with application to digital communication systems. Herein, we consider the detection/decoding problem. We aim at developing an optimal neural architecture for such a task. The definition of the optimal criterion is a fundamental step. We propose to use the mutual information (MI) of the channel input-output signal pair. The computation of the MI is a formidable task, and for the majority of communication channels it is unknown. Therefore, the MI has to be learned. For such an objective, we propose a novel neural MI estimator based on a discriminative formulation. This leads to the derivation of the mutual information neural decoder (MIND). The developed neural architecture is capable not only to solve the decoding problem in unknown channels, but also to return an estimate of the average MI achieved with the coding scheme, as well as the decoding error probability. Several numerical results are reported and compared with maximum a-posteriori (MAP) and maximum likelihood (MaxL) decoding strategies.

Index Terms—Channel decoding, statistical learning, mutual information, MAP, ML, neural networks.

I. INTRODUCTION

In digital communication systems, data detection and decoding is a fundamental task implemented at the receiver. The maximum a-posteriori (MAP) decoding approach is the optimal one to minimize the symbol or sequence error probability [1], [2]. If the channel model is known, the MAP decoder can be realized according to known algorithms. For instance, for a linear time invariant channel (LTI) with additive Gaussian noise, the decoder comprises a first stage where the channel impulse response is estimated. Then, a max-log-MAP sequence estimator algorithm is implemented. The decoding metric is essentially related to the Euclidean distance between the received and hypothesized transmitted message filtered by the channel impulse response [1]. The task becomes more intriguing for channels that cannot be easily modeled or that are unknown. In such a case, a learning strategy turns out to be an attractive solution and it can be enabled by recent advances in machine learning for communications [3]-[5].

In this paper, we derive a neural architecture for optimal decoding in an unknown channel. We propose to use the mutual information (MI) of the input-output channel pair as decoding metric. The computation of the MI is a formidable task and it is unknown in many instances. Therefore, the MI has to be learned, which can be done in principle with neural architectures [6]–[10]. Additionally, in the problem at hand, the decoder has a more specific task: it has to learn and minimize the a-posteriori information $-\log_2(p_{X|Y}(\mathbf{x}|\mathbf{y}))$ of

the transmitted codeword \mathbf{x} given the observed/received signal vector \mathbf{y} . The direct estimation of such a-posteriori information becomes then the objective. Such an estimation is possible by directly learning the conditional probability density function (pdf) $p_{X|Y}(\mathbf{x}|\mathbf{y})$ with a new estimator that exploits a discriminative model referred to as mutual information neural decoder (MIND). MIND allows not only to perform the decoding task, but also to return an estimate of the channel achievable rate and of the decoding error probability.

This paper is organized as follows. Section II presents the decoding approach principle. Section III describes the core idea about MIND. Section IV discusses two practical neural architectures. Section V explains how MIND can be exploited to estimate both the achievable rate and the decoding error probability. Numerical results for a number of scenarios are reported in Section VI. Finally, the conclusions are drawn.

II. MUTUAL INFORMATION DECODING PRINCIPLE

The considered communication system comprises an encoder, a channel, and a decoder. The encoder maps $M = 2^k$ messages of k bits into M encoded messages of n (not necessarily binary) symbols. The uncoded message is denoted with the vector **b**, while the coded message with the vector **x** belonging to the set A_x . Thus, the code rate is R = k/n bits per channel use. The channel conveys the coded message to the receiver. Without loss of generality, we can write that the received message is $\mathbf{y} = H(\mathbf{x}, \mathbf{h}, \mathbf{n})$, where the channel transfer function H implicitly models the channel internal state **h** including stochastic variables, e.g. noise, **n**. For instance, for an LTI channel with additive noise, we obtain $\mathbf{y} = \mathbf{h} * \mathbf{x} + \mathbf{n}$, where * denotes convolution.

The aim of the decoder is to retrieve the transmitted message so that to minimize the decoding error, or equivalently to maximize the received information for each transmitted message. Indeed, if we consider the mutual information of the pair (\mathbf{y}, \mathbf{x}) , with joint pdf $p_{XY}(\mathbf{x}, \mathbf{y})$, and marginals $p_X(\mathbf{x})$ and $p_Y(\mathbf{y})$, this can be written as

$$i(\mathbf{y}; \mathbf{x}) = i(\mathbf{x}) - i(\mathbf{x}|\mathbf{y}) \tag{1}$$

where $i(\mathbf{x})$ is the information of the transmitted message, $i(\mathbf{x}|\mathbf{y})$ is the a-posteriori information (residual uncertainty observing \mathbf{y}) [11]. It follows that for each transmitted message, the mutual information is maximized when the a-posteriori information is minimized. The a-posteriori information is given by

$$i(\mathbf{x}|\mathbf{y}) = -\log_2 p_{X|Y}(\mathbf{x}|\mathbf{y}) = -\log_2 \frac{p_{XY}(\mathbf{x},\mathbf{y})}{p_Y(\mathbf{y})}$$
(2)

The authors are with Universität Klagenfurt, Institute of Networked and Embedded Systems, Klagenfurt 9020, Austria, e-mail: andrea.tonello@aau.at, nunzio.letizia@aau.at.

so that the decoding criterion becomes

$$\hat{\mathbf{x}} = \operatorname*{arg\,min}_{\mathbf{x}\in\mathcal{A}_x} i(\mathbf{x}|\mathbf{y}) = \operatorname*{arg\,max}_{\mathbf{x}\in\mathcal{A}_x} \log_2 p_{X|Y}(\mathbf{x}|\mathbf{y}) \qquad (3)$$

which corresponds to the log-MAP decoding principle [1], [2].

To compute the a-posteriori information, we need to know the a-posteriori probability $p_{X|Y}(\mathbf{x}|\mathbf{y})$. If the channel transfer function can be modeled, then the decoder is realized according to known approaches. In fact, the a-posteriori probability can be explicitly calculated as $p_{X|Y}(\mathbf{x}|\mathbf{y}) =$ $p_{Y|X}(\mathbf{y}|\mathbf{x})p_X(\mathbf{x})$, i.e., from the conditional channel pdf and the coded message a-priori probability. However, for unknown channels and sources, we have to resort to a learning strategy as explained in the next section.

III. DISCRIMINATIVE FORMULATION OF MIND

In the following, we show that it is possible to design a parametric discriminator whose output leads to the estimation of the a-posteriori information. The optimal discriminator is found by maximizing an appropriately defined loss function. Before describing the proposed solution, it should be noted that in generative adversarial networks (GANs) [12] a discriminator D is used to distinguish if a sample is an original one coming from real data rather than a fake one generated by the generator G. The adversarial training pushes the discriminator $D(\mathbf{a})$ towards the optimum value [12]

$$D^*(\mathbf{a}) = \frac{p_{data}(\mathbf{a})}{p_{data}(\mathbf{a}) + p_{gen}(\mathbf{a})} \tag{4}$$

where $p_{data}(\mathbf{a})$ is the collected data pdf and $p_{gen}(\mathbf{a})$ is the generated data pdf. Hence, the output of the optimal discriminator can be used to estimate the probability density ratio

$$\frac{p_{gen}(\mathbf{a})}{p_{data}(\mathbf{a})} = \frac{1 - D^*(\mathbf{a})}{D^*(\mathbf{a})}.$$
(5)

Now, the idea is to design a discriminator that estimates the probability density ratio $p_{XY}(\mathbf{x}, \mathbf{y})/p_Y(\mathbf{y})$ and consequently the a-posteriori information as shown in (2).

The following Lemma provides an a-posteriori information estimator that exploits a discriminator trained to minimize a certain loss function. At the equilibrium, a transformation of the discriminator output yields the searched density ratio.

Lemma 1. Let $\mathbf{x} \sim p_X(\mathbf{x})$ and $\mathbf{y} \sim p_Y(\mathbf{y})$ be the channel input and output, respectively. Let $H(\cdot)$ be the channel transfer function, in general stochastic, such that $\mathbf{y} = H(\mathbf{x}, \mathbf{h}, \mathbf{n})$, with \mathbf{h} and \mathbf{n} being internal state and noise variables, respectively. If $\mathcal{J}_{MIND}(D)$ is the value function defined as

$$\mathcal{J}_{MIND}(D) = \mathbb{E}_{(\mathbf{x},\mathbf{y})\sim p_X(\mathbf{x})p_Y(\mathbf{y})} \left[\log \left(D(K,\mathbf{y}) \right) \right] \\ + \mathbb{E}_{(\mathbf{x},\mathbf{y})\sim p_{XY}(\mathbf{x},\mathbf{y})} \left[\log \left(1 - D(\mathbf{x},\mathbf{y}) \right) \right], \quad (6)$$

where K is a constant, then

$$D^*(\mathbf{x}, \mathbf{y}) = \frac{p_Y(\mathbf{y})}{p_Y(\mathbf{y}) + p_{XY}(\mathbf{x}, \mathbf{y})} = \arg\max_D \mathcal{J}_{MIND}(D),$$
(7)

and

$$i(\mathbf{x}|\mathbf{y}) = -\log\left(\frac{1 - D^*(\mathbf{x}, \mathbf{y})}{D^*(\mathbf{x}, \mathbf{y})}\right).$$
(8)

Proof. From the hypothesis of the Lemma, the value function can be rewritten as

$$\mathcal{J}_{MIND}(D) = \int_{\mathcal{T}_{\mathbf{x}}} \int_{\mathcal{T}_{\mathbf{y}}} \left[p_{XY}(K(\mathbf{x}), \mathbf{y}) \log \left(D(\mathbf{x}, \mathbf{y}) \right) + p_{XY}(\mathbf{x}, \mathbf{y}) \log \left(1 - D(\mathbf{x}, \mathbf{y}) \right) \right] d\mathbf{x} d\mathbf{y} \quad (9)$$

where $\mathcal{T} = \mathcal{T}_x \times \mathcal{T}_y$ is the domain of definition of the joint density function and $K(\mathbf{x})$ is a function that maps any \mathbf{x} into the constant value K with probability one.

To maximize $\mathcal{J}_{MIND}(D)$, a necessary and sufficient condition requires to take the derivative of the integrand with respect to D and to set it to 0, yielding the following equation in D

$$\frac{p_{XY}(K(\mathbf{x}), \mathbf{y})}{D(\mathbf{x}, \mathbf{y})} - \frac{p_{XY}(\mathbf{x}, \mathbf{y})}{1 - D(\mathbf{x}, \mathbf{y})} = 0.$$
 (10)

The solution of the above equation yields the optimum discriminator $D^*(\mathbf{x}, \mathbf{y})$ since: $p_{XY}(K(\mathbf{x}), \mathbf{y}) = p_Y(\mathbf{y})$ and $\mathcal{J}_{MIND}(D^*)$ is a maximum being the second derivative w.r.t. D a non-positive function.

Finally, at the equilibrium,

$$p_{X|Y}(\mathbf{x}|\mathbf{y}) = \frac{p_{XY}(\mathbf{x},\mathbf{y})}{p_Y(\mathbf{y})} = \frac{1 - D^*(\mathbf{x},\mathbf{y})}{D^*(\mathbf{x},\mathbf{y})},$$
(11)

therefore the thesis follows.

IV. PARAMETRIC (NEURAL NETWORK) IMPLEMENTATION

The practical implementation of MIND is realized through a neural network-based learning approach. That is, firstly a training phase is implemented. It consists of transmitting repeatedly all coded messages such that at equilibrium the aposteriori information is estimated. Then, in the testing phase, decoding can take place for each received new message by minimizing the a-posteriori conditional information. However, when $D(\mathbf{x}, \mathbf{y})$ is parameterized by a neural network, it may be difficult to maximize the value function in (6). One of the reason resides in the type of learning problem formulated in (6). In the following, we propose two different interpretations and discuss their differences.

A. Unsupervised Approach

The value function in (6), as it stands, requires the discriminator to be a scalar parameterized function which takes as input both the transmitted and received samples (\mathbf{x}, \mathbf{y}) . The resulting architecture is presented in Fig.1. Such formulation is general and can be applied to any coding scheme. In fact, it is sufficient during training to alternate the input joint samples (\mathbf{x}, \mathbf{y}) with marginal samples $(K(\mathbf{x}), \mathbf{y})$. Then, during the testing phase, decoding is accomplished by finding x that minimizes (8), for all possible coded messages x. This method can be thought as an unsupervised learning approach since no known labels are exploited in the loss function. Hence, the objective is to implicitly estimate both the joint and marginal distributions, $p_{XY}(\mathbf{x}, \mathbf{y})$ and $p_Y(\mathbf{y})$, respectively, as shown in (7). Nevertheless, it has been numerically verified that the unsupervised approach may lead to unstable training, especially for low signal-to-noise ratio (SNR) values. Therefore, another architecture is proposed below.

Fig. 1: Unsupervised discriminator architecture and relative value function. Input is fed with paired samples from the joint distribution while the output consists of a single probability ratio value.

B. Supervised Approach

Another idea consists of decomposing the value function in (6) as a sum of independent elements for every input code \mathbf{x}_i , for $i \in \{1, ..., M\}$ as follows

$$\mathcal{J}_{MIND} = \sum_{\mathbf{x}_i \in \mathcal{A}_x} \mathcal{J}_i, \tag{12}$$

where

$$\mathcal{J}_{i}(D_{i}) = \mathbb{E}_{\mathbf{y} \sim p_{Y}(\mathbf{y})} \left[\log \left(D_{i}(\mathbf{y}) \right) \right]$$

$$+ \mathbb{E}_{(\mathbf{x}_{i}, \mathbf{y}) \sim p_{Y|X}(\mathbf{y}|\mathbf{x}_{i})} \left[\log \left(1 - D_{i}(\mathbf{y}) \right) \right].$$
(13)

Given the channel input \mathbf{x}_i , we can feed the discriminator D_i with only the output channel \mathbf{y} . It is then simple to verify that the maximum of \mathcal{J}_{MIND} is obtained when

$$\frac{1 - D_i^*}{D_i^*} = \frac{p_{XY}(\mathbf{x}_i, \mathbf{y})}{p_Y(\mathbf{y})} = p_{X|Y}(\mathbf{x}_i | \mathbf{y}).$$
 (14)

From an implementation perspective, every D_i corresponds to the *i*-th output of a vector discriminator (see Fig.2) $\mathbf{D}(\cdot)$. Therefore the number of outputs in this setup depends on M and each output can be interpreted as a likelihood ratio. Finally, the multiple output architecture value function can be rewritten in a vector form as follows

$$\mathcal{J}_{MIND}(\mathbf{D}) = \mathbb{E}_{\mathbf{y} \sim p_{Y}(\mathbf{y})} \left[\log \left(\mathbf{D}(\mathbf{y}) \right) \cdot \mathbf{1}_{M} \right]$$
(15)
+ $\mathbb{E}_{(\mathbf{x}, \mathbf{y}) \sim p_{XY}(\mathbf{x}, \mathbf{y})} \left[\log \left(1 - \mathbf{D}(\mathbf{y}) \right) \cdot \mathbf{1}_{M, \mathbf{x}} \right],$

where $\mathbf{1}_M = [1, 1, \dots, 1]$ is a vector of M elements and $\mathbf{1}_{M,\mathbf{x}}$ is the one-hot code of \mathbf{x} . The new value function in (15) possesses now the label information in the scalar product with the one-hot code and therefore enjoys the property of supervised learning. In addition, the discriminator does not need to implicitly learn the joint distribution but only the conditional $p_{X|Y}(\mathbf{x}|\mathbf{y})$, which is done by the M outputs D_i .

Among the M discriminator outputs (14), and similarly to the unsupervised MAP scenario, the final decoding stage implements

$$\mathbf{\hat{x}}_{i} = \operatorname*{arg\,max}_{i \in \{1,\dots,M\}} \log_{2} \frac{1 - D_{i}^{*}}{D_{i}^{*}} = \operatorname*{arg\,min}_{\mathbf{x}_{i} \in \mathcal{A}_{x}} i(\mathbf{x}_{i} | \mathbf{y}).$$
(16)

From an information perspective, MIND aims at finding the codeword \mathbf{x}_i which minimizes the residual uncertainty $i(\mathbf{x}_i|\mathbf{y})$ after the observation of \mathbf{y} .

Fig. 2: Supervised discriminator architecture and relative value function. Input is fed with the received channel samples while the output consists of multiple probability ratio values, one for each transmitted message.

V. ESTIMATION OF ACHIEVED INFORMATION RATE AND DECODING ERROR PROBABILITY

Dealing with an unknown channel, a relevant question is the estimation of the information rate achieved with the used coding scheme. MIND can be exploited for such a goal. In fact, the normalized average mutual information (in bits per channel use) is given by [11]

$$I(X;Y) = \frac{1}{n}(H(X) - H(X|Y))$$
(17)

whose computation requires the entropy of the source H(X)and the conditional entropy H(X|Y):

$$H(X) = \mathbb{E}_{\mathbf{x} \sim p_X(\mathbf{x})}[i(\mathbf{x})] = -\sum_{\mathbf{x}_i \in \mathcal{A}_x} p_X(\mathbf{x}_i) \log_2 p_X(\mathbf{x}_i)$$
(18)
$$H(X|Y) = -\mathbb{E}_{\mathbf{x}_0, p_X(\mathbf{x})} \left[\sum_{\mathbf{y}_X \mid \mathbf{y} \in \mathbf{x}_i \in \mathbf{y}_i} p_{X|Y}(\mathbf{x}_i|\mathbf{y}) \log_2 p_{X|Y}(\mathbf{x}_i|\mathbf{y}) \right].$$

$$H(X|Y) = -\mathbb{E}_{\mathbf{y} \sim p_Y(y)} \left[\sum_{\mathbf{x}_i \in \mathcal{A}_x} p_{X|Y}(\mathbf{x}_i|\mathbf{y}) \log_2 p_{X|Y}(\mathbf{x}_i|\mathbf{y}) \right]$$
(19)

The discriminator in MIND, for a given coding scheme, returns an estimate of the a-posteriori probability $p_{X|Y}(\mathbf{x}_i|\mathbf{y}) = (1 - D_i)/D_i \ \forall i = \{1, \dots, M\}$, therefore (19) can be directly computed. About (18), it is worth mentioning that the source distribution can be obtained using Monte Carlo integration from the a-posteriori probability given by MIND, so that with a number of realizations $N \to \infty$ the source entropy becomes

$$H(X) \approx -\frac{1}{N} \sum_{\mathbf{x}_i \in \mathcal{A}_x} \sum_{j=1}^N p_{X|Y}(\mathbf{x}_i | \mathbf{y}_j) \log_2\left(\frac{1}{N} \sum_{j=1}^N p_{X|Y}(\mathbf{x}_i | \mathbf{y}_j)\right),\tag{20}$$

and similarly

$$H(X|Y) \approx -\frac{1}{N} \sum_{j=1}^{N} \sum_{\mathbf{x}_i \in \mathcal{A}_x} p_{X|Y}(\mathbf{x}_i|\mathbf{y}_j) \log_2 p_{X|Y}(\mathbf{x}_i|\mathbf{y}_j)$$
(21)

where again the "instantaneous" conditional pdf at time j is given by the MIND discriminator output.

MIND can be used also to estimate the decoding error probability P_e . Indeed,

 $P_e = 1 - P[\mathbf{x} = \hat{\mathbf{x}}] = 1 - \mathbb{E}_{\mathbf{y} \sim p_Y(y)}[p_{X|Y}(\mathbf{x} = \hat{\mathbf{x}}|\mathbf{y})],$ (22) where the probability $p_{X|Y}(\mathbf{x} = \hat{\mathbf{x}}|\mathbf{y})$ comes from the decision criterion $\max_{\mathbf{x}_i} p_{X|Y}(\mathbf{x}_i|\mathbf{y})$ which is the instantaneous probability of correct decoding. Hence, using again Monte Carlo integration

$$P_e \stackrel{N \to \infty}{=} 1 - \frac{1}{N} \sum_{j=1}^{N} \max_{\mathbf{x}_i \in \mathcal{A}_x} p_{X|Y}(\mathbf{x}_i | \mathbf{y}_j).$$
(23)

Fig. 3: a) Symbol error rate for a 4-PAM modulation with nonuniform source distribution over an AWGN channel. Comparison among the optimal MAP decoder, MaxL decoder, MIND decoder and the estimated probability of error provided by MIND. b) Estimated source and conditional entropy (top) and estimated average mutual information (bottom) using MIND.

In the next section, we compare MIND to other well-known decoding criteria in scenarios for which an analytic solution is available. Furthermore, thanks to the network ability to estimate the a-posteriori probability, the average mutual information between pairs of input-output channel samples is also reported.

VI. NUMERICAL RESULTS

The assessment of the proposed decoding approach is done by considering the following three representative scenarios: a) Uncoded transmission of symbols that are produced by a nonuniform source over an additive Gaussian noise channel; b) Uncoded transmission in a non-linear channel with additive Gaussian noise; c) Short block coded transmission in an additive Middleton noise channel.

Details about the architecture and hyper parameters of the neural networks are reported in the GitHub repository [13].

A. Non-uniform Source

To show the ability of the decoder to learn and exploit data dependence at the source, we firstly consider 4-PAM transmission with symbols $\mathbf{x}_i \in \{-3, -1, 1, 3\}$ and mass function given by a non-uniform source $p(\mathbf{x}) = [(1 - p(\mathbf{x}))]$ P/2, P/2, (1 - P)/2, P/2, with P = 0.05. It should be noted that data dependence at the source can be either created with a coding stage from a source that emits i.i.d. symbols, or intrinsically by the source of data traffic having certain statistics, as in this case. In Fig. 3a the probability of symbol error is shown. MIND is compared with the optimal MAP decoder that knows the a-priori distribution of the transmitted data symbols $p(\mathbf{x})$ and with the maximum-likelihood (MaxL) decoder that only knows the Gaussian nature of the channel and assumes a source with uniform distribution. Moreover, the estimated P_e is also shown. In Fig. 3b, the source entropy, the conditional entropy and the average achieved mutual information, as estimated by MIND, are reported. It is worth noticing that the average mutual information increases with

Fig. 4: a) Symbol error rate for a 4-PAM modulation with uniform source distribution over a non-linear channel affected by additive Gaussian noise. Comparison among MaxL decoder with no CSI, MaxL decoder with perfect CSI, MIND decoder and the estimated probability of error provided by MIND. b) Estimated source and conditional entropy (top) and estimated average mutual information (bottom) using MIND.

the SNR, or alternatively, the residual uncertainty introduced by the channel decreases. In addition, the estimated source entropy tends to stabilize around its real value given by $P \log_2(P/2) - (1-P) \log_2((1-P)/2)$.

B. Non-linear Channel

As a second example, we consider 4-PAM uncoded transmission with uniform source distribution over a non-linear channel with additive Gaussian noise. The objective of this experiment is to show the ability of MIND to discover such a channel non-linearity. In particular, the channel introduces a non-linearity (for instance because of the presence of nonlinear amplifiers) modeled as $y_k = \operatorname{sign}(x_k) \sqrt{|x_k|} + n_k$, where k denotes the k-th time instant. Fig.4a demonstrates how the MIND decoder has managed to implicitly learn the nonlinear channel model during the training phase and effectively use such information during decoding. A comparison with the MaxL decoder with and without perfect channel state information (CSI) knowledge is also conducted. Results show that MIND exhibits performance close to optimality. Fig. 4b illustrates both the behaviour of the entropies and the average mutual information as function of the SNR.

C. Additive Non-gaussian Noise Channel

Lastly, and perhaps as most interesting example, we consider a short block coded transmission over an additive nongaussian channel. The aim is to assess the ability of MIND to learn and exploit the presence of non-gaussian noise. In particular, we suppose that the noise follows a truncated Middleton distribution [14], also called Bernoulli-Gaussian noise model, so that at any given time instant k it is obtained as $n_k = (1 - \epsilon_k)n_{1,k} + \epsilon_k n_{2,k}$ where $n_{1,k} \sim \mathcal{N}(0, \sigma_b^2)$ is a zero-mean Gaussian random variable with variance σ_b^2 and $n_{2,k} \sim \mathcal{N}(0, B\sigma_b^2)$ is also a zero-mean Gaussian random variable but with variance B times larger. Instead, ϵ_k is a Bernoulli random variable with probability of success P. The pdf of the noise samples is then given by

$$p_N(\mathbf{n}_k) = (1 - P)\mathcal{N}(0, \sigma_b^2) + P\mathcal{N}(0, B\sigma_b^2).$$
 (24)

Fig. 5: Bit error rate and mutual information of a short block coded transmission in an additive Middleton noise channel: a) Repetition code; b) Hamming code; c) Convolutional code.

Assuming that the noise model is known and that BPSK symbols are transmitted, two decoding strategies can be devised. The first, denoted with MaxL Middleton, uses maximum likelihood decoding with the known conditional pdf $p(\mathbf{y}|\mathbf{x}) = p_N(\mathbf{y} - \mathbf{x})$. The second strategy is a genie decoder that knows the outcome of the Bernoulli event for every time instance. That is, it knows whether a received sample is hit by Gaussian noise with variance σ_h^2 or $B\sigma_h^2$. A third decoding strategy is offered by MIND that learns the channel statistics. We distinguish among three different types of codes: a) a binary repetition code with length 5; b) a (7,4) Hamming code; c) a rate 1/2 convolutional code with memory 2 and block-length 18. For each of them, the bit error rate (BER) obtained with the genie, the MaxL Middleton and the MIND decoders is reported. The parameter B was set to 5 in all the experiments involving Middleton noise, wherein we also set P = 0.05. Fig.5 shows the gain provided by the neuralbased decoder scheme over the classical maximum likelihood one that exploits the Middleton distribution in (24). With MIND, the BER performance gets closer to the genie decoder. Furthermore, Fig.5 also reports an estimate of the average mutual information provided by MIND.

VII. CONCLUSIONS

In this paper, MIND, a neural decoder that uses the mutual information as decoding criterion, has been proposed. Two specific architectures have been described and they are capable of learning the conditional information $i(\mathbf{x}|\mathbf{y})$ of the codeword \mathbf{x} given the channel output observation \mathbf{y} in unknown channels. Additionally, MIND allows the estimation of the achieved information rate with the used coding scheme as well as the decoding error probability. Several numerical results obtained in illustrative channels show that MIND can achieve the performance of the genie MAP decoder that perfectly knows the channel model and source distribution. It outperforms the conventional max-log decoder that assumes the presence of Gaussian noise.
