

Well Posedness of Utility Maximization Problems Under Partial Information in a Market with Gaussian Drift

Abdelali Gabih · Hakam Kondakji · Ralf Wunderlich

Version of May 19, 2022

Abstract This paper investigates well posedness of utility maximization problems for financial markets where stock returns depend on a hidden Gaussian mean reverting drift process. Since that process is potentially unbounded well posedness cannot be guaranteed for utility functions which are not bounded from above. For power utility with relative risk aversion smaller than those of log-utility this leads to restrictions on the choice of model parameters such as the investment horizon and parameters controlling the variance of the asset price and drift processes. We derive sufficient conditions to the model parameters leading to bounded maximum expected utility of terminal wealth for models with full and partial information.

Keywords Utility maximization, Partial information, Well posedness, Stochastic optimal control, Ornstein-Uhlenbeck process

1 Introduction

In this paper we investigate utility maximization problems for a financial market where asset prices follow a diffusion process with an unobservable Gaussian mean reverting drift modelled by an Ornstein-Uhlenbeck process. It is a companion paper to [14] where we examine in detail the maximization of expected power utility of terminal wealth which is treated as a stochastic optimal control problem under partial information. A special feature of that paper is that for the construction of optimal portfolio strategies investors estimate the unknown drift not only from observed asset prices. They also incorporate external sources of information such as news, company reports, ratings or their own intuitive views on the future asset performance. These outside sources of information are called expert opinions.

In the present paper we focus on the well posedness of the above stochastic control problem which in the literature is often overlooked or taken for granted. For Gaussian drift processes which are potentially unbounded well posedness in general cannot be guaranteed for utility functions which are not bounded from above. This is the case for log-utility and power utility with relative risk aversion smaller than those of log-utility. For log-utility well posedness can be shown quite easily and holds without restriction to the model parameters. However, the case of power utility is much more demanding and leads to restrictions on the choice of model parameters such as the investment horizon and parameters controlling the variance of the asset price and drift processes. This phenomenon was already observed in Kim and Omberg [15] for a financial market with an observable drift modeled by an Ornstein-Uhlenbeck process. They coined the terminology *nirvana strategies*. Such strategies generate in finite time a terminal wealth with a distribution leading to infinite expected utility. Note that this is a property of the distribution of terminal wealth and realizations of terminal wealth need not to be infinite. The same holds for the generating strategies which might be even suboptimal. That phenomenon was also observed in Korn and Kraft [17, Sec. 3] who coined it “I-unstability”, in Angoshtari [1,2] who studied power utility maximization problems and their well posedness for financial market models with cointegrated asset price processes and in Battauz et al. [3] for markets with defaultable assets. Kim and Omberg also pointed out that financial market models allowing investors to attain nirvana do not properly reflect reality. Thus, there are not only mathematical reasons to exclude combinations of model parameters allowing for attaining nirvana, i.e., not ensuring well posed optimization problems. This problem is addressed in the present paper and we derive sufficient conditions to the model parameters leading to bounded maximum expected utility of terminal wealth.

Portfolio selection problems for market models with partial information on the drift have been intensively studied in the last years. We refer to Lakner [18] and Brendle [5] for models with Gaussian drift and to Rieder and Bäuerle [19], Sass and Haussmann [20] for models in which the drift is described by a continuous-time hidden Markov chain. A generalization of these approaches and further references can be found in Björk et al. [4].

Utility maximization problems for investors with logarithmic preferences in market models with non-observable Gaussian drift process and discrete-time expert opinions are addressed in a series of papers [12,13,21,22,23] of the present authors and of Sass and Westphal. The case of continuous-time expert opinions and power utility maximization is treated in a series of papers by Davis and Lleo, see [7,8]. For models with drift processes described by continuous-time hidden Markov chains and power utility maximization we refer to Frey et al. [10,11]. Finally, explicit solutions of the power utility maximization problem addressed in this paper can be found in our our companion paper [14].

The paper is organized as follows. In Section 2 we introduce the financial market model with partial information of the drift and formulate the portfolio optimization problem. The well posedness of that problem is studied in Section 3. The main result is Theorem 3.3 providing an upper bound for the expected terminal wealth expressed in terms of the solution to some matrix Riccati differential equation and involving the initial value of the non-observable drift. That results allows to deduce sufficient conditions to the model parameters ensuring the well posedness of the utility maximization problem under full information. The respective conditions for the case of partial information follow from the projection the above upper bound on the σ -algebra representing the initial information of

the partially informed investor. These conditions become quite explicit for market models with a single risky asset which are considered in Subsection 3.4. Section 4 illustrates the theoretical findings by results of some numerical experiments and visualize the derived restrictions on the model parameters. The appendix collects proofs which are removed from the main text.

Notation. Throughout this paper, we use the notation I_d for the identity matrix in $\mathbb{R}^{d \times d}$, 0_d denotes the null vector in \mathbb{R}^d , $0_{d \times m}$ the null matrix in $\mathbb{R}^{d \times m}$. For a symmetric and positive-semidefinite matrix $A \in \mathbb{R}^{d \times d}$ we call a symmetric and positive-semidefinite matrix $B \in \mathbb{R}^{d \times d}$ the *square root* of A if $B^\top B = A$. The square root is unique and will be denoted by $A^{1/2}$. For a generic process X we denote by \mathbb{G}^X the filtration generated by X .

2 Financial Market and Optimization Problem

2.1 Price Dynamics

We model a financial market with one risk-free and multiple risky assets. The setting is based on Gabih et al. [12, 13] and Sass et al. [21, 23, 22]. For a fixed date $T > 0$ representing the investment horizon, we work on a filtered probability space $(\Omega, \mathcal{G}, \mathbb{G}, \mathbb{P})$, with filtration $\mathbb{G} = (\mathcal{G}_t)_{t \in [0, T]}$ satisfying the usual conditions. All processes are assumed to be \mathbb{G} -adapted.

We consider a market model for one risk-free bond with constant price $S_t^0 = 1$ and d risky securities whose return process $R = (R^1, \dots, R^d)$ is defined by

$$dR_t = \mu_t dt + \sigma_R dW_t^R, \quad (2.1)$$

for a given d_1 -dimensional \mathbb{G} -adapted Brownian motion W^R with $d_1 \geq d$. The volatility matrix $\sigma_R \in \mathbb{R}^{d \times d_1}$ is assumed to be constant over time such that $\Sigma_R := \sigma_R \sigma_R^\top$ is positive definite. In this setting the price process $S = (S^1, \dots, S^d)$ of the risky securities reads as

$$dS_t = \text{diag}(S_t) dR_t, \quad S_0 = s_0, \quad (2.2)$$

with some fixed initial value $s_0 = (s_0^1, \dots, s_0^d)$. Note that for the solution to the above SDE it holds

$$\log S_t^i - \log s_0^i = \int_0^t \mu_s^i ds + \sum_{j=1}^{d_1} \left(\sigma_R^{ij} W_t^{R,j} - \frac{1}{2} (\sigma_R^{ij})^2 t \right) = R_t^i - \frac{1}{2} \sum_{j=1}^{d_1} (\sigma_R^{ij})^2 t, \quad i = 1, \dots, d.$$

So we have the equality $\mathbb{G}^R = \mathbb{G}^{\log S} = \mathbb{G}^S$. This is useful since it allows to work with R instead of S in the filtering part.

The dynamics of the drift process $\mu = (\mu_t)_{t \in [0, T]}$ in (2.1) are given by the stochastic differential equation (SDE)

$$d\mu_t = \kappa(\bar{\mu} - \mu_t) dt + \sigma_\mu dW_t^\mu, \quad (2.3)$$

where $\kappa \in \mathbb{R}^{d \times d}$, $\sigma_\mu \in \mathbb{R}^{d \times d_2}$ and $\bar{\mu} \in \mathbb{R}^d$ are constants such that the matrices κ and $\Sigma_\mu := \sigma_\mu \sigma_\mu^\top$ are positive definite, and W^μ is a d_2 -dimensional Brownian motion such that $d_2 \geq d$. For the sake of simplification and shorter notation we assume that the Wiener processes W^R and W^μ driving the return and drift process, respectively, are independent. We refer to

Brendle [5], Colaneri et al. [6] and Fouque et al. [9] for the general case. Here, $\bar{\mu}$ is the mean-reversion level, κ the mean-reversion speed and σ_μ describes the volatility of μ . The initial value μ_0 is assumed to be a normally distributed random variable independent of W^μ and W^R with mean $\bar{m}_0 \in \mathbb{R}^d$ and covariance matrix $\bar{q}_0 \in \mathbb{R}^{d \times d}$ assumed to be symmetric and positive semi-definite.

2.2 Expert Opinions

We assume that investors observe the return process R but they neither observe the factor process μ nor the Brownian motion W^R . They do however know the model parameters such as $\sigma_R, \kappa, \bar{\mu}, \sigma_\mu$ and the distribution $\mathcal{N}(\bar{m}_0, \bar{q}_0)$ of the initial value μ_0 . Information about the drift μ can be drawn from observing the returns R . A special feature of our model is that investors may also have access to additional information about the drift in form of *expert opinions* such as news, company reports, ratings or their own intuitive views on the future asset performance. The expert opinions provide noisy signals about the current state of the drift arriving at known deterministic time points $0 = t_0 < t_1 < \dots < t_{N-1} < T$. For the sake of convenience we also write $t_N = T$ although no expert opinion arrives at time t_N . The signals or “expert views” at time t_k are modelled by \mathbb{R}^d -valued Gaussian random vectors $Z_k = (Z_k^1, \dots, Z_k^d)^\top$ with

$$Z_k = \mu_{t_k} + \Gamma^{\frac{1}{2}} \varepsilon_k, \quad k = 0, \dots, n-1, \quad (2.4)$$

where the matrix $\Gamma \in \mathbb{R}^{d \times d}$ is symmetric and positive definite. Further, $(\varepsilon_k)_{k=0, \dots, n-1}$ is a sequence of independent standard normally distributed random vectors, i.e., $\varepsilon_k \sim \mathcal{N}(0, I_d)$. It is also independent of both the Brownian motions W^R, W^μ and the initial value μ_0 of the drift process. Thus given μ_{t_k} the expert opinion Z_k is $\mathcal{N}(\mu_{t_k}, \Gamma)$ -distributed. So, Z_k can be considered as an unbiased estimate of the unknown state of the drift at time t_k . The matrix Γ is a measure of the expert’s reliability. Its diagonal entries Γ^{ii} are just the variances of the expert’s estimate of the drift component μ^i at time t_k . The larger Γ^{ii} the less reliable is the expert’s estimate.

Note that one may also allow for relative expert views where experts give an estimate for the difference in the drift of two stocks instead of absolute views. This extension can be studied in Schöttle et al. [24] where the authors show how to switch between these two models for expert opinions by means of a pick matrix.

In addition to expert opinions arriving at discrete time points we also consider expert opinions arriving continuously over time as in the BLCT model of Davis and Lleo [7, 8]. This is motivated by the results of Sass et al. [22] who show that for increasing arrival intensity λ and an expert’s variance Γ growing linearly in λ asymptotically for $\lambda \rightarrow \infty$ the information drawn from these expert opinions is essentially the same as the information one gets from observing yet another diffusion process. This diffusion process can then be interpreted as an expert who gives a continuous-time estimation about the current state of the drift. Let this estimate be given by the diffusion process

$$dJ_t = \mu_t dt + \sigma_J dW_t^J \quad (2.5)$$

where W_t^J is a d_3 -dimensional Brownian motion independent of W_t^R and W_t^μ and such that with $d_3 \geq d$. The volatility matrix $\sigma_J \in \mathbb{R}^{d \times d_3}$ is assumed to be constant over time such that

the matrix $\Sigma_J := \sigma_J \sigma_J^\top$ is positive definite. In [14] we show that based on this model and on the diffusion approximations provided in [23, 22] one can find efficient approximative solutions to utility maximization problems for partially informed investors observing high-frequency discrete-time expert opinions.

2.3 Investor Filtration

We consider various types of investors with different levels of information. The information available to an investor is described by the *investor filtration* $\mathbb{F}^H = (\mathcal{F}_t^H)_{t \in [0, T]}$. Here, H denotes the information regime for which we consider the cases $H = R, Z, J, F$, where

$$\begin{aligned}\mathbb{F}^R &= (\mathcal{F}_t^R)_{t \in [0, T]} \text{ with } \mathcal{F}_t^R = \sigma(R_s, s \leq t) \vee \mathcal{F}_0^I, \\ \mathbb{F}^Z &= (\mathcal{F}_t^Z)_{t \in [0, T]} \text{ with } \mathcal{F}_t^Z = \sigma(R_s, s \leq t, (t_k, Z_k), t_k \leq t) \vee \mathcal{F}_0^I, \\ \mathbb{F}^J &= (\mathcal{F}_t^J)_{t \in [0, T]} \text{ with } \mathcal{F}_t^J = \sigma(R_s, J_s, s \leq t) \vee \mathcal{F}_0^I, \\ \mathbb{F}^F &= (\mathcal{F}_t^F)_{t \in [0, T]} \text{ with } \mathcal{F}_t^F = \sigma(R_s, \mu_s, s \leq t).\end{aligned}$$

We assume that the σ -algebras \mathcal{F}_t^H are augmented by the null sets of P . Above we denote by \mathcal{F}_0^I the σ -algebra representing the initial information of the partially informed investors ($H = R, J, Z$) about μ_0 . We assume that at $t = 0$ these investors start with the same initial information, i.e., $\mathcal{F}_0^H = \mathcal{F}_0^I \subset \mathcal{F}_0^F$, $H = R, J, Z$. This initial information \mathcal{F}_0^I models prior knowledge about the drift process at time $t = 0$, e.g., from observing returns or expert opinions in the past before the trading period $[0, T]$. We assume that the conditional distribution of the initial value drift μ_0 given \mathcal{F}_0^H is the normal distribution $\mathcal{N}(m_0, q_0)$ with mean $m_0 \in \mathbb{R}^d$ and covariance matrix $q_0 \in \mathbb{R}^{d \times d}$ assumed to be symmetric and positive semi-definite. For typical examples we refer to the companion paper [14, Sec. 2.3]

We call the investor with filtration $\mathbb{F}^H = (\mathcal{F}_t^H)_{t \in [0, T]}$ the H -investor. The R -investor observes only the return process R , the Z -investor combines return observations with the discrete-time expert opinions Z_k while the J -investor observes the return process together with the continuous-time expert J . Finally, the F -investor has full information and can observe the drift process μ . For stochastic drift this case is not realistic, but we use it as a benchmark. It will serve as a limiting case for high-frequency expert opinions with fixed covariance matrix Γ . We will denote an investor with investor filtration \mathbb{F}^H as H -investor.

2.4 Portfolio and Optimization Problem

We describe the self-financing trading of an investor by the initial capital $x_0 > 0$ and the \mathbb{F}^H -adapted trading strategy $\pi = (\pi_t)_{t \in [0, T]}$ where $\pi_t \in \mathbb{R}^d$. Here π_t^i represents the proportion of wealth invested in the i -th stock at time t . The assumption that π is \mathbb{F}^H -adapted models that investment decisions have to be based on information available to the H -investor which he obtains from observing assets prices ($H = R$) combined with expert opinions ($H = Z, J$) or with the drift process ($H = F$). Following the strategy π the investor generates a wealth process $(X_t^\pi)_{t \in [0, T]}$ whose dynamics reads as

$$\frac{dX_t^\pi}{X_t^\pi} = \pi_t^\top dR_t = \pi_t^\top \mu_t dt + \pi_t^\top \sigma_R dW_t^R, \quad X_0^\pi = x_0. \quad (2.6)$$

We denote by

$$\mathcal{A}_0^H = \left\{ \pi = (\pi_t)_t : \pi_t \in \mathbb{R}^d, \pi \text{ is } \mathbb{F}^H\text{-adapted}, X_t^\pi > 0, \mathbb{E} \left[\int_0^T \|\pi_t\|^2 dt \right] < \infty \right\} \quad (2.7)$$

the class of *admissible trading strategies*. We assume that the investor wants to maximize the expected utility of terminal wealth for a given utility function $U : \mathbb{R}_+ \rightarrow \mathbb{R}$ modelling the risk aversion of the investor. In our approach we will use the function

$$\mathcal{U}_\theta(x) := \frac{x^\theta}{\theta}, \quad \theta \in (-\infty, 0) \cup (0, 1). \quad (2.8)$$

The limiting case for $\theta \rightarrow 0$ for the power utility function leads to the logarithmic utility $\mathcal{U}_0(x) := \ln x$, since we have $\mathcal{U}_\theta(x) - \frac{1}{\theta} = \frac{x^\theta - 1}{\theta} \xrightarrow{\theta \rightarrow 0} \log x$. The optimization problem thus reads as

$$\mathcal{V}_0^H(x_0) := \sup_{\pi \in \mathcal{A}_0^H} \mathcal{D}_0^H(x_0; \pi) \quad \text{where} \quad \mathcal{D}_0^H(x_0; \pi) = \mathbb{E} [\mathcal{U}_\theta(X_T^\pi) \mid \mathcal{F}_0^H, X_0^\pi = x_0], \quad \pi \in \mathcal{A}_0^H, \quad (2.9)$$

where we call $\mathcal{D}_0^H(x_0; \pi)$ *reward function* or *performance criterion* of the strategy π and $\mathcal{V}_0^H(x_0)$ *value function* to given initial capital x_0 . This is for $H \neq F$ a maximization problem under partial information since we have required that the strategy π is adapted to the investor filtration \mathbb{F}^H while the drift coefficient of the wealth equation (2.6) is not \mathbb{F}^H -adapted, it depends on the non-observable drift μ . Note that for $x_0 > 0$ the solution of the SDE (2.6) is strictly positive. This guarantees that X_T^π is in the domain of logarithmic and power utility.

3 Well Posedness of the Optimization Problem

3.1 Well Posedness

Solving the utility maximization problem (2.9) for the various information regimes $H = R, Z, J, F$ requires conditions under which the optimization problem is well posed. Under these conditions the maximum expected utility of terminal wealth cannot explode in finite time as it is the case for so-called nirvana strategies described in Kim and Omberg [15] and Angoshtari [1]. Such strategies generate in finite time a terminal wealth with a distribution leading to infinite expected utility although the realizations of terminal wealth may be finite.

We start by describing the model of the financial market via the parameter

$$\rho := \{T, \theta, d, \sigma_R, \sigma_\mu, \kappa, \bar{\mu}, x_0, \bar{m}_0, \bar{q}_0, m_0, q_0\} \quad (3.1)$$

taking values in a suitable chosen set of parameter values \mathcal{P} . For emphasizing the dependence on the parameter ρ we rewrite (2.9) as

$$\mathcal{V}_0^H(\rho) := \sup_{\pi \in \mathcal{A}_0^H} \mathcal{D}_0^H(\rho; \pi) \quad \text{where} \quad \mathcal{D}_0^H(\rho; \pi) = \mathbb{E} [\mathcal{U}_\theta(X_T^\pi) \mid \mathcal{F}_0^H, \rho], \quad \pi \in \mathcal{A}_0^H. \quad (3.2)$$

Compared to notation in (2.9) this is a slight abuse of notation but it facilitates the study the dependence of the reward and value function on *all* model parameters contained in ρ and not only on one of its components, the initial wealth x_0 . For a given parameter ρ we want to study if the performance criterion of the optimization problem (2.9) is well-defined in the following sense.

Definition 3.1 *For a given financial market with parameter $\rho \in \mathcal{P}$ we say that the utility maximization problem (3.2) for the H -investor is well-posed, if there exists a constant $C_{\mathcal{V}}^H = C_{\mathcal{V}}^H(\rho) < \infty$ depending on ρ such that*

$$\mathcal{V}_0^H(\rho) \leq C_{\mathcal{V}}^H.$$

The set

$$\mathcal{P}^H = \{\rho \in \mathcal{P} : \text{problem (3.2) is well posed}\} \subset \mathcal{P}$$

is called set of feasible parameters of the financial market model for which (3.2) is well-posed.

3.2 Log-Utility and Power Utility with $\theta < 0$

For power utility with parameter $\theta < 0$ it holds $\mathcal{U}_\theta(x) < 0$. Hence, in that case we can choose $C_{\mathcal{V}}^H = 0$ and the optimization problem is well-posed for all model parameters $p \in \mathcal{P}$ with $\theta < 0$. For log-utility ($\theta = 0$) the utility function is no longer bounded from above but as we show in our companion paper [14, Subsec. 4.1] the value function $\mathcal{V}_0^H(x_0)$ is bounded from above by some positive constant $C_{\mathcal{V}}^H$ for any selection of the remaining model parameters in $\rho \in \mathcal{P}$. Hence it holds $\{\rho \in \mathcal{P} : \theta \leq 0\} \subset \mathcal{P}^H$. More challenging is the case of power utility with positive parameter $\theta \in (0, 1)$ which is also not bounded from above. That case is investigated in the remainder of this section. We note that this approach can also be applied to log-utility leading to an alternative proof of well posedness for the maximization of expected log-utility, for details we refer to Kondakji [16, Sec. 4.2].

3.3 Power Utility with $\theta \in (0, 1)$

For the study of well posedness it will be convenient to extend the concept of the fully informed F -investor who has access to observations of the return and drift process to an (artificial) investor who observes also expert opinions. That investor is called G -investor and defined by the investor filtration $\mathbb{F}^G = \mathbb{G}$ which is the underlying filtration to which all stochastic process of the financial market model are adapted. Comparing the F - and G -investor the additional information from the observation of expert opinions (and the driving Wiener processes W^R, W^μ, W^J) will not lead to superior performance of the G -investor in the considered utility maximization problem but it leads to the inclusion $\mathbb{F}^H \subset \mathbb{F}^G$ for $H = R, Z, J, F$. Note that for the F -investor we only have $\mathbb{F}^R \subset \mathbb{F}^F$ but in general $\mathbb{F}^Z, \mathbb{F}^J \not\subset \mathbb{F}^F$. Analogous to the other investors we define for $H = G$ the set of admissible strategies \mathcal{A}_0^G , the performance criterion \mathcal{D}_0^G and the value function \mathcal{V}_0^G as in (2.7) and (3.2), respectively.

Next we want to derive estimates of the value function \mathcal{V}_0^H of the H -investor in terms of the value function \mathcal{V}_0^G of the G -investor. Let us fix a strategy $\pi \in \mathcal{A}_0^H$, then tower property

of the conditional expectation with $\mathcal{F}_0^H \subset \mathcal{F}_0^G$ implies

$$\mathcal{D}_0^H(\rho; \pi) = \mathbb{E}[\mathcal{U}_\theta(X_T^\pi) | \mathcal{F}_0^H] = \mathbb{E}[\mathbb{E}[\mathcal{U}_\theta(X_T^\pi) | \mathcal{F}_0^G] | \mathcal{F}_0^H] = \mathbb{E}[\mathcal{D}_0^G(\rho; \pi) | \mathcal{F}_0^H]. \quad (3.3)$$

Taking supremum on both sides and using $\mathcal{A}_0^H \subset \mathcal{A}_0^G$ we obtain

$$\begin{aligned} \mathcal{V}_0^H(\rho) &= \sup_{\pi \in \mathcal{A}_0^H} \mathcal{D}_0^H(\rho; \pi) = \sup_{\pi \in \mathcal{A}_0^H} \mathbb{E}[\mathcal{D}_0^G(\rho; \pi) | \mathcal{F}_0^H] \leq \mathbb{E}[\sup_{\pi \in \mathcal{A}_0^G} \mathcal{D}_0^G(\rho; \pi) | \mathcal{F}_0^H] \\ &\leq \mathbb{E}[\sup_{\pi \in \mathcal{A}_0^G} \mathcal{D}_0^G(\rho; \pi) | \mathcal{F}_0^H] = \mathbb{E}[\mathcal{V}_0^G(\rho) | \mathcal{F}_0^H]. \end{aligned} \quad (3.4)$$

In the sequel we will derive conditions under which $\mathcal{V}_0^G(\rho)$ is bounded. Then estimate (3.4) will allow us to derive conditions for the boundedness of $\mathcal{V}_0^H(\rho)$ for the other information regimes H . We will need the following lemma where we denote by $\mu_u^{t,m}$ the drift at time $u \in [t, T]$ starting at time $t \in [0, T]$ from $m \in \mathbb{R}^d$.

Lemma 3.2 *Let $\gamma \in \mathbb{R} \setminus \{0\}$, $t \in [0, T]$, $z > 0$ and the stochastic process $(\Psi_s^{t,z,m})_{s \in [t, T]}$ be defined by*

$$\Psi_s^{t,z,m} := z \exp \left\{ \gamma \int_t^s (\mu_u^{t,m})^\top \Sigma_R^{-1} \mu_u^{t,m} du \right\} \quad (3.5)$$

and the function $d : [0, T] \times \mathbb{R}^d \rightarrow \mathbb{R}_+$ be defined by $d(t, m) := \mathbb{E}[\Psi_T^{t,1,m}]$, for $t \in [0, T]$ and $m \in \mathbb{R}^d$. Then it holds

$$d(t, m) := \exp \left\{ m^\top A_\gamma(t) m + B_\gamma^\top(t) m + C_\gamma(t) \right\}. \quad (3.6)$$

Here $A_\gamma(t)$, $B_\gamma(t)$ and $C_\gamma(t)$ are functions in $t \in [0, T]$ taking values in $\mathbb{R}^{d \times d}$, \mathbb{R}^d and \mathbb{R} , respectively, satisfying the following system of ODEs

$$\frac{dA_\gamma(t)}{dt} = -2A_\gamma(t) \Sigma_\mu A_\gamma(t) + \kappa^\top A_\gamma(t) + A_\gamma(t) \kappa - \gamma \Sigma_R^{-1}, \quad A_\gamma(T) = 0_{d \times d}, \quad (3.7)$$

$$\frac{dB_\gamma(t)}{dt} = -2A_\gamma(t) \kappa \bar{\mu} + \left[\kappa^\top - 2A_\gamma(t) \Sigma_\mu \right] B_\gamma(t), \quad B_\gamma(T) = 0_d, \quad (3.8)$$

$$\frac{dC_\gamma(t)}{dt} = -\frac{1}{2} B_\gamma^\top(t) \Sigma_\mu B_\gamma(t) - B_\gamma^\top(t) \kappa \bar{\mu} - \text{tr} \{ \Sigma_\mu A_\gamma(t) \}, \quad C_\gamma(T) = 0. \quad (3.9)$$

Proof. The proof is given in Appendix A.

Note that equation (3.7) is a Riccati equation for symmetric matrix-valued function A_γ while equation (3.8) is a system of d linear differential equations whose solution B_γ is obtained given A_γ . Finally given A_γ and B_γ the function scalar function C_γ is obtained by integrating the right hand side of (3.9).

Theorem 3.3 *For a model parameter ρ with $\theta \in (0, 1)$ the value function of the G -investor satisfies*

$$\mathcal{V}_0^G(\rho) \leq \frac{x_0^\theta}{\theta} d^{1-\theta}(0, \mu_0),$$

where the function $d : [0, T] \times \mathbb{R}^d \rightarrow \mathbb{R}_+$ is given by (3.6) for $\gamma = \frac{\theta}{2(1-\theta)^2}$ and μ_0 is the initial value of the drift.

Proof. The proof is given in Appendix B.

The last theorem together with the fact that for $\theta \leq 0$ the problem is well posed (see the reasoning at the beginning of this section) allows to give the following characterization of the G -investor's set \mathcal{P}^G of feasible model parameters by the inclusion $\underline{\mathcal{P}}^G \subset \mathcal{P}^G$ where

$$\underline{\mathcal{P}}^G = \{\rho \in \mathcal{P} : \theta \in (0, 1) \text{ and } d(0, \mu_0) \text{ given in (3.6) is bounded}\} \cup \{\rho \in \mathcal{P} : \theta \leq 0\}. \quad (3.10)$$

We are now in a position to characterize the set of feasible model parameters \mathcal{P}^H for $H = R, Z, J, F$ by substituting the estimate for $\mathcal{V}_0^G(\rho)$ from Theorem 3.3 into (3.4) yielding

$$\mathcal{V}_0^H(\rho) \leq \frac{x_0^\theta}{\theta} \mathbb{E}[d(0, \mu_0) | \mathcal{F}_0^H]. \quad (3.11)$$

Well posedness for full information ($H = F$). For the F -Investor the drift is known and from the above inequality it follows

$$\mathcal{V}_0^F(\rho) \leq \frac{x_0^\theta}{\theta} \mathbb{E}[d(0, \mu_0) | \mathcal{F}_0^F] = \frac{x_0^\theta}{\theta} d(0, \mu_0),$$

which implies that the inclusion given in (3.10) for \mathcal{P}^G also holds for the set of feasible model parameters \mathcal{P}^F for the F -investor.

The restrictions in (3.10) to the feasible model parameters ρ for $\theta \in (0, 1)$ are given implicitly via the boundedness of $d(0, \mu_0)$ where d is given in view of (3.6). They can be further analysed by studying conditions for non-explosive solutions of Riccati equation (3.7) for the matrix-valued function A_γ on the investment horizon $[0, T]$. The boundedness of the solution to (3.7) carries over to the boundedness of the solution to the linear differential equation (3.8) for B_γ and also to C_γ which is obtained by integrating the right hand side of (3.9). Thus we obtain

Corollary 3.4 (Sufficient condition for well posedness, full information)

The utility maximization problem (3.2) for the fully informed F -investor is well-posed for all parameters $\rho \in \underline{\mathcal{P}}^F \subset \mathcal{P}^F$ where

$$\underline{\mathcal{P}}^H = \left\{ \rho \in \mathcal{P} : \theta \in (0, 1), \text{ for } \gamma = \frac{\theta}{2(1-\theta)^2} \text{ is } A_\gamma \text{ bounded on } [0, T] \right\} \cup \{\rho \in \mathcal{P} : \theta \leq 0\}. \quad (3.12)$$

It is well known that in general closed-form solutions of Riccati differential equations are available only for the one-dimensional case ($d = 1$). More details about this special case can be found below in Subsec. 3.4.

Well posedness for partial information ($H = R, Z, J$). For the partially informed investors the random variable $d(0, \mu_0)$ in (3.11) is no longer \mathcal{F}_0^H -measurable and we have to compute the conditional expectation using the conditional distribution of the initial drift value μ_0 given \mathcal{F}_0^H . The result is given below in Theorem 3.6 for which we need the following lemma. The proofs can be found in Appendix C and D, respectively.

Lemma 3.5 *Let $Y \sim \mathcal{N}(\mu_Y, \Sigma_Y)$ be a d -dimensional Gaussian random vector, $U \in \mathbb{R}^{d \times d}$ a symmetric and invertible matrix such that $I_d - 2U\Sigma_Y$ is positive definite and $b \in \mathbb{R}^d$. Then it holds*

$$\mathbb{E} \left[\exp \{ (Y + b)^\top U (Y + b) \} \right] = (\det(I_d - 2U\Sigma_Y))^{-1/2} \times \exp \{ (\mu_Y + b)^\top (I_d - 2U\Sigma_Y)^{-1} U (\mu_Y + b) \}. \quad (3.13)$$

Theorem 3.6 *Let for $H = R, Z, J$ the conditional distribution of the initial value of the drift μ_0 given \mathcal{F}_0^H be the normal distribution $\mathcal{N}(m_0, q_0)$ with mean $m_0 \in \mathbb{R}^d$ and covariance matrix $q_0 \in \mathbb{R}^{d \times d}$. Further assume that $K = I_d - 2A_\gamma(0)q_0$ for $\gamma = \frac{\theta}{2(1-\theta)^2}$ is positive definite. Then it holds*

$$\mathcal{V}_0^H(\rho) \leq \frac{x_0^\theta}{\theta} C_V^H \quad \text{with} \quad C_V^H = d(0, m_0) (\det(K))^{-1/2} \exp \left\{ \frac{1}{2} a^\top q_0 K^{-1} a \right\}, \quad (3.14)$$

where $a := 2A_\gamma(0)m_0 + B_\gamma(0)$.

From the above theorem we deduce the following sufficient condition for well posedness.

Corollary 3.7 (Sufficient condition for well posedness, partial information)

The utility maximization problem (3.2) for the partially informed H -investor, $H = R, J, Z$, is well-posed for all parameters $\rho \in \underline{\mathcal{P}}^H \subset \mathcal{P}^H$ where

$$\underline{\mathcal{P}}^H = \left\{ \rho \in \mathcal{P} : \theta \in (0, 1), \text{ for } \gamma = \frac{\theta}{2(1-\theta)^2} \text{ is } A_\gamma \text{ bounded on } [0, T] \text{ and } I_d - 2A_\gamma(0)q_0 \text{ positive definite} \right\} \cup \{ \rho \in \mathcal{P} : \theta \leq 0 \}. \quad (3.15)$$

For $\theta \in (0, 1)$ well posedness can be guaranteed for a model parameter ρ for which the Riccati equation (3.7) has a bounded solution on $[0, T]$ and if the initial value of the conditional covariance q_0 is not “too large” such that K is positive definite. While the first condition already implies the well posedness for the problem under full information the latter condition is an additional restriction for the partially informed case. Note that for $H = F$ we can set $q_0 = 0$ which yields the positive definite matrix $K = I_d$. Further we note that the specific model settings for the observations available to the the partially informed investor do not play a role for the well posedness except the initial conditional covariance q_0 .

3.4 Market Models With a Single Risky Asset

The above conditions for the well posedness given in terms of the boundedness of $d(0, \mu_0)$ and $A_\gamma(0)$ are quite abstract and its verification requires that the solution of the Riccati ODE (3.7) is bounded on $[0, T]$. While in the multi-dimensional case Riccati ODEs in general can be solved only numerically these equations enjoy a closed-form solution in the one-dimensional case. This allows to give more explicit characterizations of the set of feasible parameters for market models with a single risky asset only. The following lemma gives explicit conditions to the model parameters under which (3.7) has a bounded solution on $[0, T]$. For the proof we refer to Kondakji [16, Lemma A.1.3, A.2.2 and A.2.3]

Lemma 3.8 Let $d = 1$, $\theta \in (0, 1)$, $\gamma = \frac{\theta}{2(1-\theta)^2}$ and

$$\Delta_\gamma = 4\kappa^2 \left(1 - 2\gamma \left(\frac{\sigma_\mu}{\kappa\sigma_R}\right)^2\right) \quad \text{and} \quad \delta_\gamma := \frac{1}{2} \sqrt{|\Delta_\gamma|}. \quad (3.16)$$

Then it holds for the Riccati differential equation (3.7) on $[0, T]$

1. For $\Delta_\gamma \geq 0$ there is a bounded solution for all $T > 0$.
2. For $\Delta_\gamma < 0$ a bounded solution exists only if $T < T_\gamma^E$ with the explosion time

$$T^E := \frac{1}{\delta_\gamma} \left(\frac{\pi}{2} + \arctan \frac{\kappa}{\delta_\gamma} \right). \quad (3.17)$$

The above lemma allows to give more explicit sufficient conditions for well posedness given for the general multi-dimensional case in Corollary 3.4 and 3.7. They can be formulated in terms of the parameters $\kappa, \sigma_\mu, \sigma_R$ describing the variance of the asset price and drift process, the investment horizon T , the parameter θ of the utility function and the initial conditional variance q_0 . Analyzing the inequality $T < T^E$ and (3.17) we obtain

Corollary 3.9 (Sufficient condition for well posedness, single risky asset)

Let $d = 1$, $\gamma = \frac{\theta}{2(1-\theta)^2}$ and $\Delta_\gamma, T_\gamma^E$ as given in (3.16) and (3.17), respectively.

1. The utility maximization problem (3.2) for the **fully informed** F -investor is well-posed for all parameters $\rho \in \underline{\mathcal{P}}^F \subset \mathcal{P}^F$ where

$$\begin{aligned} \underline{\mathcal{P}}^F = & \{ \rho \in \mathcal{P} : \theta \in (0, 1), \kappa, \sigma_\mu, \sigma_R \text{ such that } \Delta_\gamma \geq 0 \} \cup \\ & \{ \rho \in \mathcal{P} : \theta \in (0, 1), \kappa, \sigma_\mu, \sigma_R \text{ such that } \Delta_\gamma < 0 \text{ and } T < T_\gamma^E \} \cup \{ \rho \in \mathcal{P} : \theta \leq 0 \}. \end{aligned} \quad (3.18)$$

2. The utility maximization problem (3.2) for the **partially informed** H -investor, $H = R, J, Z$, is well-posed for all parameters $\rho \in \underline{\mathcal{P}}^H \subset \mathcal{P}^H$ where

$$\begin{aligned} \underline{\mathcal{P}}^F = & \{ \rho \in \mathcal{P} : \theta \in (0, 1), \kappa, \sigma_\mu, \sigma_R \text{ such that } \Delta_\gamma \geq 0, q_0 < (2A_\gamma(0))^{-1} \} \cup \\ & \{ \rho \in \mathcal{P} : \theta \in (0, 1), \kappa, \sigma_\mu, \sigma_R \text{ such that } \Delta_\gamma < 0 \text{ and } T < T_\gamma^E, q_0 < (2A_\gamma(0))^{-1} \} \cup \\ & \{ \rho \in \mathcal{P} : \theta \leq 0 \}. \end{aligned} \quad (3.19)$$

4 Numerical Results

In this section we illustrate the theoretical findings of the previous sections by results of some numerical experiments. They are based on a stock market model where the unobservable drift $(\mu_t)_{t \in [0, T]}$ follows an Ornstein-Uhlenbeck process as given in (2.3) whereas the volatility is known and constant. For simplicity, we assume that there is only one risky asset in the market, i.e. $d = 1$. If not stated otherwise our numerical experiments are based on model parameters as given in Table 4.1.

In Section 3 we have specified sufficient conditions to the model parameters for which the optimization problem is well-posed. For market models with a single risky asset which is assumed for the numerical experiments these conditions are given Corollary 3.9. In Figure 4.1 we visualize the subset $\underline{\mathcal{P}}^F$ of the set of feasible parameters \mathcal{P}^F for which well

Drift	mean reversion level	$\bar{\mu}$	0	Investment horizon	T	1 year
	mean reversion speed	κ	3	Power utility parameter	θ	0.3
	volatility	σ_{μ}	1	Volatility of stock	σ_R	0.25
	mean of μ_0	\bar{m}_0	$\bar{\mu} = 0$	Initial estimate	$m_0 = \bar{m}_0$	0
	variance of μ_0	\bar{q}_0	$\frac{\sigma_{\mu}^2}{2\kappa} = 0.1\bar{6}$		$q_0 = \bar{q}_0$	$0.1\bar{6}$

Table 4.1 Model parameters for the numerical experiments

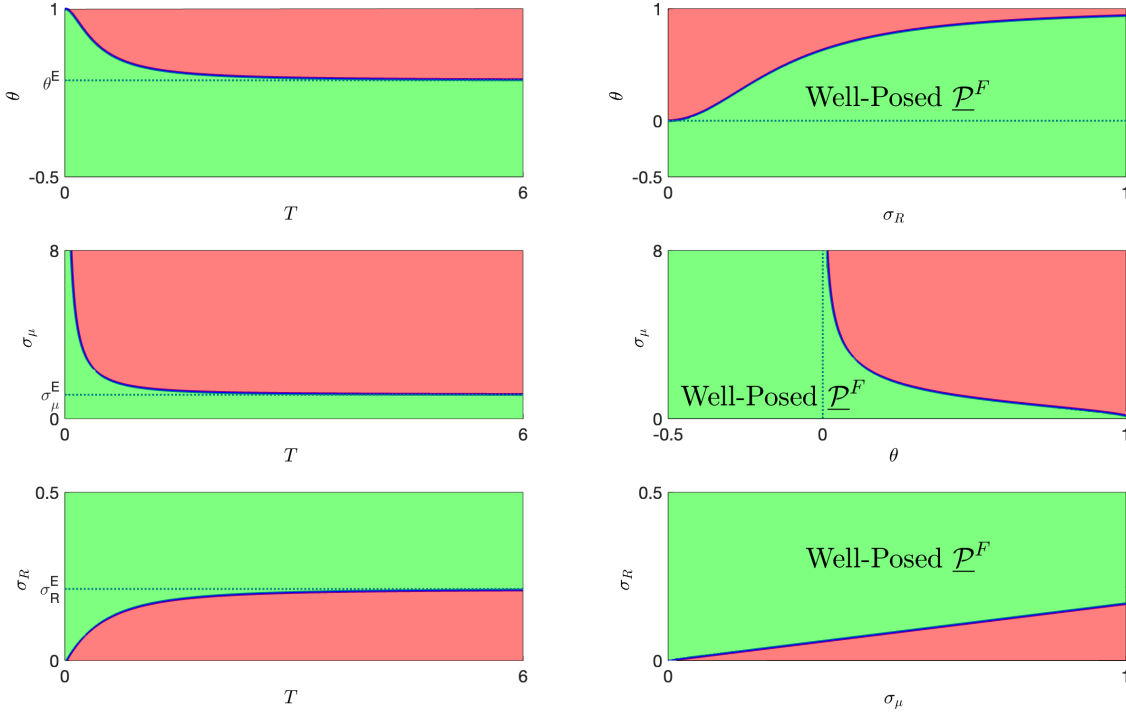

Fig. 4.1 Subset $\underline{\mathcal{P}}^F$ of the set of feasible parameters \mathcal{P}^F depending on θ and T (top left), θ and σ_R (top right), σ_{μ} and T (middle left), σ_{μ} and θ (middle right), σ_R and T (bottom left), σ_R and σ_{μ} (bottom right). The other parameters are given in Table 4.1.

posedness for the utility maximization problem of the fully informed investor can be guaranteed. In particular, we show the dependence of \mathcal{P}^F on the investment horizon T , the power utility parameter θ , the volatility σ_{μ} of the drift and the volatility σ_R of the stock price.

The two top panels show the subset $\underline{\mathcal{P}}^F$ depending on θ , T and σ_R . It can be seen that for negative θ , i.e. for investors which are more risk averse than the log-utility investor, the optimization problem is always well-posed. Moreover, the top left panel shows that for the selected parameters the optimization problem is well-posed for all $T > 0$ if the parameter θ does not exceed the critical value $\theta^E \approx 0.36$. For $\theta > \theta^E$, i.e. for investors with sufficiently small risk-aversion, the optimization problem is no longer well-posed for all investment horizons T , but only up to a critical investment horizon $T^E = T^E(\theta)$ depending on θ and given in (3.17). The larger θ , the smaller is that critical investment horizon $T(\theta)$. For the

limiting case $\theta \rightarrow 1$ it holds $T^E(\theta) \rightarrow 0$. The top right panel shows for an investment horizon fixed to $T = 1$ the subset $\underline{\mathcal{P}}^F$ depending on θ volatility σ_R of stock price. It can be seen that larger values for the stock volatility allow to choose larger values of θ .

The two panels in the middle illustrate the influence of the drift volatility σ_μ on the subset $\underline{\mathcal{P}}^F$. The left panel shows that the optimization problem is well-posed for all $T > 0$ as long as the volatility σ_μ of the drift does not exceed the critical value $\sigma_\mu^E \approx 1.15$. For volatilities $\sigma_\mu > \sigma_\mu^E$ the optimization problem is well-posed only for investment horizons T smaller than the critical horizon $T^E = T^E(\sigma_\mu)$ that depends on σ_μ and is given in (3.17).

In the right panel we investigate for fixed investment horizon $T = 1$ the dependence of \mathcal{P}^F on the drift volatility σ_μ and the power utility parameter θ . While for $\theta < 0$ there are no further restrictions on the parameters, this is no longer true for $\theta \in (0, 1)$. The larger the volatility σ_μ the smaller one has to choose θ .

The bottom two panels illustrate the influence of stock volatility σ_R on the subset $\underline{\mathcal{P}}^F$. In contrast to the volatility σ_μ of the drift, smaller values of σ_R imply that the optimization problem is well-posed only for smaller T as it can be seen in the bottom left panel. If σ_R does not exceed the critical value $\sigma_R^E \approx 0.22$, then the optimization problem is well-posed only up to a critical investment horizon $T^E = T^E(\sigma_R)$ that depends on σ_R . The larger σ_R , the larger the horizon can be set. However, for σ_R exceeding the critical value σ_R^E the control problem is well defined for any horizon time $T > 0$. The bottom right panel shows the dependence of \mathcal{P}^F on the two volatilities σ_R and σ_μ . Note that the two regions are separated by a straight line as it can be deduced from (3.16) and (3.17).

Finally, we consider the case of a partial informed investor. Then an additional condition on the initial covariance q_0 of the filter has to imposed to ensure well posedness. We refer to Corollary 3.7 for the multi-dimensional case and to Corollary 3.9 and (3.19) for the special case of markets with a single risky asset. That condition requires that $1 - 2A_\gamma(0)q_0 > 0$ which is satisfied for the the model parameters from Table 4.1 since $q_0 = 0.16 < 0.675 = \frac{1}{2A_\gamma(0)}$.

A Proof of Lemma 3.2

Proof. Consider first the function $D \in \mathcal{C}^{1,2}$ defined as follows

$$D : [0, T] \times \mathbb{R}^+ \times \mathbb{R}^d \rightarrow \mathbb{R}_+; \quad D(t, z, m) := \mathbb{E} [\Psi_T^{t,z,m}]. \quad (\text{A.1})$$

Then it holds $D(T, z, m) = \mathbb{E} [\xi_T^{T,z,m}] = \mathbb{E} [z] = z$.

The dynamics of the drift μ and the process Ψ for $s \in [t, T]$ read as

$$\begin{pmatrix} d\mu_s^{t,m} \\ d\Psi_s^{t,z,m} \end{pmatrix} = \begin{pmatrix} \kappa(\bar{\mu} - \mu_s^{t,m}) \\ \gamma \Psi_s^{t,z,m} (\mu_s^{t,m})^\top \Sigma_R^{-1} \mu_s^{t,m} \end{pmatrix} ds + \begin{pmatrix} \sigma_\mu \\ 0_{1 \times d_2} \end{pmatrix} dW_s^\mu; \quad \begin{pmatrix} \mu_t^{t,m} \\ \Psi_t^{t,z,m} \end{pmatrix} = \begin{pmatrix} m \\ z \end{pmatrix}.$$

The drift and the diffusion coefficients of the last equation satisfy the Lipschitz- and linear growth conditions. Moreover, the Feynman-Kac-Formula for the expectation from (A.1) leads to the following partial differential equation for D

$$0 = \frac{\partial}{\partial t} D(t, z, m) + \nabla_m^\top D(t, z, m) \kappa(\bar{\mu} - m) + \frac{1}{2} \text{tr} \{ \nabla_{mm} D(t, z, m) \Sigma_\mu \} + \gamma z m^\top \Sigma_R^{-1} m \frac{\partial G_b(t, z, m)}{\partial z} \quad (\text{A.2})$$

with $D(T, z, m) = z$ as terminal condition. The above terminal value problem can be solved with the following separation ansatz

$$D(t, z, m) = z d(t, m), \quad d(T, m) = 1. \quad (\text{A.3})$$

At time t we have $\mu_t^{t,m} = m$ and $\Psi_t^{t,1,m} = 1$ so that we obtain $\mathbb{E}[\Psi_T^{t,1,m}] = D(t, 1, m) = d(t, m)$ which is the function d defined in Lemma (3.2). Plugging (A.3) into (A.2) leads to the following linear parabolic PDE for d

$$0 = \frac{\partial}{\partial t} d(t, m) + \nabla_m^\top d(t, m) \kappa(\bar{\mu} - m) + \frac{1}{2} \text{tr} \{ \nabla_{mm} d(t, m) \Sigma_\mu \} + \gamma m^\top \Sigma_R^{-1} m d(t, m)$$

with terminal value $d(T, m) = 1$. For solving the above PDE the ansatz

$$d(t, m) = \exp \{ m^\top A_\gamma(t) m + B_\gamma^\top(t) m + C_\gamma(t) \}.$$

leads to the system of ODEs for A_γ , B_γ and C_γ , which are given in (3.7), (3.8) and (3.9).

B Proof of Theorem 3.3

Proof. In the proof we follow an approach presented in Angoshtari [1, Theorem 1.8]. Let $(\xi_t)_{t \in [0, T]}$ be a stochastic process satisfying the SDE

$$d\xi_t = \xi_t \mu_t^\top \Sigma_R^{-1} \sigma_R dW_t^R, \quad \xi_0 = 1, \quad \mu_0 = \bar{m}_0, \quad (\text{B.1})$$

with the solution

$$\xi_t = \exp \left\{ -\frac{1}{2} \int_0^t \|\mu_s^\top \Sigma_R^{-1} \sigma_R\|^2 ds - \int_0^t \mu_s^\top \Sigma_R^{-1} \sigma_R dW_s^R \right\}. \quad (\text{B.2})$$

For $t_0 \in [0, T]$ we denote by $\mu_t^{t_0, \bar{m}}$ the solution to the drift equation (2.3) starting at time t_0 with initial value \bar{m} , by $X_t^{\pi, t_0, x, \bar{m}}$ the solution to the wealth equation (2.6) with initial values (x, \bar{m}) and by $\xi_t^{t_0, z, \bar{m}}$ the solution of (B.1) at time t with initial values (z, \bar{m}) . Applying Itô's-formula it holds

$$\begin{aligned} d\langle X^{\pi, 0, x, \bar{m}_0} \xi^{0, 1, \bar{m}_0} \rangle_t &= X_t^{\pi, 0, x, \bar{m}_0} d\xi_t^{0, 1, \bar{m}_0} + \xi_t^{0, 1, \bar{m}_0} dX_t^{\pi, 0, x, \bar{m}_0} + d\langle X^{\pi, 0, x, \bar{m}_0}, \xi^{0, 1, \bar{m}_0} \rangle_t \\ &= \xi_t^{0, 1, \bar{m}_0} X_t^{\pi, 0, x, \bar{m}_0} [\pi_t^\top \sigma_R - \mu_t^{0, \bar{m}_0} \Sigma_R^{-1} \sigma_R] dW_t^R. \end{aligned} \quad (\text{B.3})$$

Moreover, Fatou's Lemma implies that the non-negative process $(X^\pi \xi)_t$ is a supermartingal, and as consequence it holds

$$x - \mathbb{E}[X_T^{\pi, 0, x, \bar{m}_0} \xi_T^{0, 1, \bar{m}_0}] \geq 0. \quad (\text{B.4})$$

From the other hand let $f : \mathbb{R}^+ \rightarrow \mathbb{R}$ be the associated Legendre-Fenchel-Transformation of the utility function $\mathcal{U}_\theta(x)$ defined for every $w > 0$ by

$$f(w) := \sup_{x \in \mathbb{R}^+} \{ \mathcal{U}_\theta(x) - xw \} = \frac{1 - \theta}{\theta} w^{-\frac{\theta}{1-\theta}}. \quad (\text{B.5})$$

Since $\xi_T^{0, 1, \bar{m}_0} > 0$, it holds for every $w > 0$

$$f(\xi_T^{0, 1, \bar{m}_0} w) = \sup_{x \in \mathbb{R}^+} \left\{ \mathcal{U}_\theta(x) - x \xi_T^{0, 1, \bar{m}_0} w \right\} \geq \mathcal{U}_\theta(X_T^{\pi, 0, x, \bar{m}_0}) - X_T^{\pi, 0, x, \bar{m}_0} \xi_T^{0, 1, \bar{m}_0} w. \quad (\text{B.6})$$

Now for $w > 0$ inequality (B.4) implies that

$$\begin{aligned} \mathbb{E}[\mathcal{U}_\theta(X_T^{\pi,0,x,\bar{m}_0})] &\leq \mathbb{E}[\mathcal{U}_\theta(X_T^{\pi,0,x,\bar{m}_0})] + w(x - \mathbb{E}[X_T^{\pi,0,x,\bar{m}_0} \xi_T^{0,1,\bar{m}_0}]) \\ &= \mathbb{E}[\mathcal{U}_\theta(X_T^{\pi,0,x,\bar{m}_0}) - X_T^{\pi,0,x,\bar{m}_0} \xi_T^{0,1,\bar{m}_0} w] + xw \\ &\leq \mathbb{E}[f(\xi_T^{0,1,\bar{m}_0} w)] + xw, \end{aligned}$$

where the last inequality follows from (B.6). For the term $f(\xi_T^{0,1,\bar{m}_0} w)$ we now apply (B.5) to obtain

$$\mathbb{E}[\mathcal{U}_\theta(X_T^{\pi,0,x,\bar{m}_0})] \leq \frac{1-\theta}{\theta} w^{-\frac{\theta}{1-\theta}} \mathbb{E}[(\xi_T^{0,1,\bar{m}_0})^{-\frac{\theta}{1-\theta}}] + xw. \quad (\text{B.7})$$

Since the last inequality holds for every admissible strategy $\pi \in \mathcal{A}^G$ and for every $w > 0$, we can take the supremum over all strategies $\pi \in \mathcal{A}^G$ on the left-hand side and the infimum over all $w > 0$ in the right-hand side to obtain

$$\mathcal{V}_0^G = \sup_{\pi \in \mathcal{A}^G} \mathbb{E}[\mathcal{U}_\theta(X_T^{\pi,0,x,\bar{m}_0})] \leq \frac{1}{\theta} x^\theta (\mathbb{E}[(\xi_T^{0,1,\bar{m}_0})^{-\frac{\theta}{1-\theta}}])^{1-\theta}. \quad (\text{B.8})$$

The problem is now reduced to investigate if the expectation in the r.h.s. of (B.8) is bounded. It holds

$$(\xi_T^{0,1,m})^{-\frac{\theta}{1-\theta}} = \exp\left\{\frac{\theta}{1-\theta} \left(\frac{1}{2} \int_0^T \|(\mu_s^{0,m})^\top \Sigma_R^{-1} \sigma_R\|^2 ds + \int_0^T (\mu_s^{0,m})^\top \Sigma_R^{-1} \sigma_R dW_s^R\right)\right\} = \Lambda_T \cdot \Psi_T^{0,1,m},$$

where $\Psi_T^{0,1,m}$ is given in (3.5) with $\gamma = \frac{\theta}{2(1-\theta)^2}$, and the term Λ_T is given by

$$\Lambda_T = \exp\left\{\int_0^T \frac{\theta}{1-\theta} (\mu_s^{0,m})^\top \Sigma_R^{-1} \sigma_R dW_s^R - \frac{1}{2} \int_0^T \left\| \frac{\theta}{1-\theta} (\mu_s^{0,m})^\top \Sigma_R^{-1} \sigma_R \right\|^2 ds\right\}.$$

We now introduce a new probability measure P^* given by $\frac{dP^*}{dP} = \Lambda_T$ so that the expectation from (B.8) can be expressed as follows

$$\mathbb{E}\left[(\xi_T^{0,1,m})^{-\frac{\theta}{1-\theta}}\right] = \mathbb{E}[\Lambda_T \cdot \Psi_T^{0,1,m}] = \mathbb{E}^*[\Psi_T^{0,1,m}] = d(0, m).$$

This expectation can be expressed according to (3.6) in Lemma 3.2, where \mathbb{E}^* denotes the expectation under the new probability measure.

C Proof of Lemma 3.5

Proof. It holds

$$\mathbb{E}[\exp\{(Y+b)^\top U(Y+b)\}] = ((2\pi)^d \det(\Sigma_Y))^{-1/2} \int_{\mathbb{R}^d} \exp\{f_Y(y)\} dy \quad (\text{C.1})$$

with $f_Y(y) := -\frac{1}{2}(y - \mu_Y)^\top \Sigma_Y^{-1}(y - \mu_Y) + (y+b)^\top U(y+b)$. Quadratic complement with respect to y with the notation $\Sigma_Z := (\Sigma_Y^{-1} - 2U)^{-1}$ and $\mu_Z := \Sigma_Z(2Ub + \Sigma_Y^{-1}\mu_Y)$ yields

$$\begin{aligned} f_Y(y) &= -\frac{1}{2}(y - \mu_Z)^\top \Sigma_Z^{-1}(y - \mu_Z) + \frac{1}{2}\mu_Z^\top \Sigma_Z^{-1}\mu_Z + b^\top Ub - \frac{1}{2}\mu_Y^\top \Sigma_Y^{-1}\mu_Y \\ &= -\frac{1}{2}(y - \mu_Z)^\top \Sigma_Z^{-1}(y - \mu_Z) + (\mu_Y + b)^\top (I_d - 2U\Sigma_Y)^{-1}U(\mu_Y + b). \end{aligned} \quad (\text{C.2})$$

Substituting (C.2) into (C.1) and using that for a Gaussian random vector $Z \sim \mathcal{N}(\mu_Z, \Sigma_Z)$ the probability density function is $f_Z(y) = ((2\pi)^d \det(\Sigma_Z))^{-1/2} \exp\{-\frac{1}{2}(y - \mu_Z)^\top \Sigma_Z^{-1}(y - \mu_Z)\}$ with $\int_{\mathbb{R}^d} f_Z(x) dx = 1$ and the relation $(\det(\Sigma_Z))^{1/2} \det(\Sigma_Y)^{-1/2} = (\det(\Sigma_Y^{-1} - 2U) \det(\Sigma_Y))^{-1/2} = (\det(I_d - 2U\Sigma_Y))^{-1/2}$ proves the assertion.

D Proof of Theorem 3.6

Proof. We recall (3.11) stating $\mathcal{V}_0^H(\rho) \leq \frac{x_0^0}{\theta} \mathbb{E}[d(0, \mu_0) | \mathcal{F}_0^H]$. For the H -investors with $H = R, J, Z$ the conditional distribution of μ_0 given \mathcal{F}_0^H is the Gaussian distribution $\mathcal{N}(m_0, q_0)$. Thus we can write the conditional expectation $\mathbb{E}[d(0, \mu_0) | \mathcal{F}_0^H]$ as $\mathbb{E}[d(0, m_0 + q_0^{1/2} \varepsilon)]$ with a random variable $\varepsilon \sim \mathcal{N}(0, I_d)$ independent of \mathcal{F}_0^H . To simplify the notation we write in the following A, B, C instead of $A_\gamma(0), B_\gamma(0), C_\gamma(0)$, respectively. Substituting into (3.11) and using representation (3.6) we deduce

$$\begin{aligned} \mathbb{E}[d(0, \mu_0) | \mathcal{F}_0^H] &= \mathbb{E}[d(0, m_0 + q_0^{1/2} \varepsilon)] \\ &= \mathbb{E}[\exp\{(m_0 + q_0^{1/2} \varepsilon)^\top A(m_0 + q_0^{1/2} \varepsilon) + B^\top(m_0 + q_0^{1/2} \varepsilon) + C\}] \\ &= \mathbb{E}[\exp\{m_0^\top A m_0 + B^\top m_0 + C\} \exp\{(q_0^{1/2} \varepsilon)^\top A q_0^{1/2} \varepsilon + (2m_0^\top A + B^\top) q_0^{1/2} \varepsilon\}] \\ &= d(0, m_0) \mathbb{E}[\exp\{(q_0^{1/2} \varepsilon)^\top A q_0^{1/2} \varepsilon + (2A m_0 + B)^\top q_0^{1/2} \varepsilon\}] \\ &= d(0, m_0) \exp\left\{-\frac{1}{4} a^\top A^{-1} a\right\} \mathbb{E}[\exp\{Y^\top A Y\}] \end{aligned} \quad (\text{D.1})$$

where $Y = q_0^{1/2} \varepsilon + \frac{1}{2} A^{-1} a \sim \mathcal{N}(\mu_Y, \Sigma_Y)$ is a Gaussian random vector with mean $\mu_Y = \frac{1}{2} A^{-1} a$ and covariance matrix $\Sigma_Y = q_0$. We recall that $a = 2A m_0 + B$ and $K = I_d - 2A q_0$. Applying Lemma 3.5 with $U = A$ and $b = 0_d$ yields

$$\mathbb{E}[\exp\{Y^\top A Y\}] = (\det(K))^{-1/2} \exp\{\mu_Y^\top K^{-1} A \mu_Y\}$$

and we obtain from (D.1)

$$\mathbb{E}[d(0, \mu_0) | \mathcal{F}_0^H] = d(0, m_0) (\det(K))^{-1/2} \exp\left\{\mu_Y^\top K^{-1} A \mu_Y - \frac{1}{4} a^\top A^{-1} a\right\} \quad (\text{D.2})$$

Rearranging terms in the exponent using the symmetry of A yields

$$\begin{aligned} \mu_Y^\top K^{-1} A \mu_Y - \frac{1}{4} a^\top A^{-1} a &= \frac{1}{4} a^\top A^{-1} K^{-1} a - \frac{1}{4} d^\top A^{-1} d \\ &= \frac{1}{4} a^\top A^{-1} (I_{d \times d} - K) K^{-1} a = \frac{1}{4} a^\top A^{-1} 2A q_0 K^{-1} a = \frac{1}{2} a^\top q_0 K^{-1} a. \end{aligned}$$

Substituting into (D.2) and (3.11) proves the claim.
