

Semi-Blind Joint Channel and Symbol Estimation for IRS-Assisted MIMO Systems

Gilderlan T. de Araújo, André L. F. de Almeida, *Senior Member, IEEE*, Rémy Boyer, *Senior Member, IEEE*, and Gábor Fodor, *Senior Member, IEEE*

Abstract—Intelligent reflecting surface (IRS) is a promising technology for the 6th generation of wireless systems, realizing the smart radio environment concept. In this paper, we present a novel tensor-based receiver for IRS-assisted multiple-input multiple-output communications capable of jointly estimating the channels and the transmitted data streams in a semi-blind fashion. Assuming a fully passive IRS architecture and introducing a simple space-time coding scheme at the transmitter, the received signal model can be advantageously built using the PARATUCK tensor model, which can be seen as a hybrid of parallel factor analysis and Tucker models. Exploiting the algebraic structure of the PARATUCK tensor model, a semi-blind receiver is derived. The proposed receiver is based on a trilinear alternating least squares method that iteratively estimates the two involved – IRS-base station and user terminal-IRS – communication channels and the transmitted symbol matrix. We discuss identifiability conditions that ensure the joint semi-blind recovery of the involved channel and symbol matrices, and propose a joint design of the coding and IRS reflection matrices to optimize the receiver performance. For the proposed semi-blind receiver, the derivation of the expected Cramér-Rao lower bound is also provided. A numerical performance evaluation of the proposed receiver design corroborates its superior performance in terms of the normalized mean squared error of the estimated channels and the achieved symbol error rate.

Index Terms—Intelligent reflecting surface, channel estimation, symbol estimation, MIMO, tensor modeling, PARATUCK, semi-blind receiver.

I. INTRODUCTION

Intelligent reflecting surface (IRS) or reconfigurable intelligent surface is a promising technology for 6th generation (6G) wireless systems [1]. An IRS consists of a two-dimensional array of a large number of passive or semi-passive elements, each of which can independently and dynamically tune the desired phase shift and amplitude of the incident radio waves [2], [3]. An immediate and simplified application of IRS is

to overcome the blockage problem between the transmitter and intended receivers in wireless networks, which reduces the dead zone¹ [6]. Due to its ability to shape the propagation environment, IRSs can be employed in various scenarios to achieve several other goals as well, as it is discussed in [7]. However, deploying IRSs in wireless communication systems involves a number of challenges, including channel state information (CSI) acquisition [3], [8], [9].

Acquiring CSI is an important issue, since the accuracy of the channel estimate has a direct impact on the gains obtained by IRS-assisted communications. The difficulty is in part due to the passive nature of the surface and the high number of reconfigurable elements. Recent works have proposed channel estimation (CE) methods to IRS-assisted communications. These works can be classified according to the IRS architecture, system setup and signal processing methodology [10]. For example, regarding the IRS architecture, it can be assumed that the IRS is fully passive, i.e., it does not have signal processing capabilities and cannot send/process pilot sequences, as it was pointed out in [11], which investigates CE in the context of IRS-assisted Terahertz communication. Alternatively, the IRS can be semi-passive, where some IRS elements are equipped with a few radio-frequency (RF) chains to facilitate the CE, as in [12].²

In the system setup category, single and multiuser systems – depending on whether the communication links are assisted by a single or multiple IRSs – can be distinguished. As an example, the authors in [13] and [14] consider a multiuser system, and the CE solution is based on an anchoring scheme, where two nodes are positioned near the IRS in order to aid the base station (BS). Also, references [15]–[18] propose CE strategies, in which multi-stage or multi-time scale estimation techniques are exploited. A double IRS-assisted system is considered in [19], in which CE and a passive beamforming design are investigated.

Recently, several mechanisms based on deep learning and compressed sensing to acquire CSI have been proposed [20], [21]. The conventional least squares (LS) CE is assumed in [22], where a minimum variance unbiased estimator is

¹Although a dead zone can be surpassed using relay technology, an IRS can be more advantageous in terms of cost since, as opposed to amplify-and-forward (AF) or decode-and-forward (DF) relays that require a dedicated power source, IRS does not require power-hungry radio-frequency chains and can also be wirelessly powered by an external RF-based source [4]. The key differences and similarities between IRS and relays are discussed in [5].

²Note that a fully passive architecture is more challenging, since the estimation of the cascaded channel, TX-IRS-Rx, or the individual channels Tx-IRS and IRS-Rx channels should be carried out at the receiver or transmitter.

proposed. In [23], channel training is divided into I blocks. Each block provides a partial channel estimate in the LS sense, so that the total channel matrix is accomplished once all blocks are processed. Paper [24] proposes a matrix factorization method based on eigenvalue decomposition (EVD). A tensor based solution for IRS-assisted multiple-input multiple-output (MIMO) systems is proposed in [25]. That method relies on a parallel factor analysis (PARAFAC) modeling of the received signals. It is shown that decoupled estimates of the involved MIMO communication channels can be obtained iteratively or in closed form. The works [26] and [27] also exploit tensor modeling to solve the CE task in IRS-assisted downlink multi-user systems. The use of tensor methods has been investigated in several previous works in the context of point-to-point [28]–[31] and cooperative (relay-assisted) MIMO systems [32]–[34]. The success of tensor-based methods comes from the powerful uniqueness properties of tensor decompositions compared to matrix-based ones. Moreover, in wireless communications, tensor-based algorithms efficiently exploit the multi-dimensional nature of the received signals in the time, space, and frequency domains. This multi-dimensional characterization of the received signals leads to more flexible transceiver designs than those offered by conventional matrix-based solutions. Recognizing these benefits of tensor-based algorithms, this paper takes a different approach compared to previous works, and provides joint estimates of the involved communication channels and the transmitted symbols in a semi-blind fashion.

Assuming a fully passive surface architecture and introducing a simple space-time coding scheme at the transmitter, we recast the received signal as a PARATUCK tensor model, which can be seen as a hybrid of PARAFAC and Tucker models [35]–[38]. Exploiting the algebraic structure of the PARATUCK tensor model, namely, the different matrix unfoldings of the received signal tensor, a semi-blind receiver based on a trilinear alternating least squares (TALS) estimation scheme is proposed. Our receiver design iteratively estimates the two involved (IRS-BS and user terminal (UT)-IRS) communication channels and the symbol matrix. Moreover, by resorting to the identifiability results of the PARATUCK tensor model, we derive useful system design recommendations that ensure the joint semi-blind recovery of the involved channel and the symbol matrices. In particular, we propose a joint design of the coding matrix and the IRS reflection matrix to optimize the receiver performance. We also present an extension of the proposed receiver algorithm to a scenario, in which the direct link is available. In this scenario, an initial estimation of the transmitted symbol matrix obtained from the direct link is used as a warm start to enhance the semi-blind joint channel and symbol estimation *via* the IRS-assisted link. Finally, we provide expressions for the expected Cramér-Rao lower bound (CRB) for the proposed semi-blind receiver.

In the following, we summarize the main contributions of this work.

- We present a novel tensor-based semi-blind receiver algorithm for IRS-assisted MIMO systems that avoids the *a priori* training phase. The proposed algorithm iteratively estimates the two involved channel matrices as well as the

symbol matrix by means of a TALS algorithm, which exploits a PARATUCK tensor model for the received signals.

- We extend the proposed semi-blind receiver to a scenario, in which the direct link between transmitter and receiver is available. In this case, the receiver processing has two stages. In the first one, an initial semi-blind estimate of the transmitted symbols obtained *via* the direct link is used as a warm start of the joint channel and symbol estimation *via* the IRS-assisted link.
- We derive conditions for the joint channel and symbol identifiability, and discuss the design of the coding matrix and the IRS phase shift matrix. A joint design is proposed to improve the receiver performance.
- We investigate the impact of the direct channel estimation on the accuracy of the IRS-assisted channel estimation, showing that a good estimate of the direct channel in the first stage improves the performance of the joint channel and symbol estimate in the second stage.
- We derive the expected CRB for the proposed TALS-PARATUCK semi-blind receivers, allowing to study its performance analytically.

Notation and properties: Matrices are represented with boldface capital letters (\mathbf{A}), and vectors are denoted by boldface lowercase letters (\mathbf{a}). Tensors are symbolized by calligraphic letters (\mathcal{A}). Transpose and pseudo-inverse of a matrix \mathbf{A} are denoted as \mathbf{A}^T and \mathbf{A}^\dagger , respectively. $D_i(\mathbf{A})$ is a diagonal matrix holding the i th row of \mathbf{A} on its main diagonal. The operator $\text{diag}(\mathbf{a})$ forms a diagonal matrix out of its vector argument, while $*$, \circ , \diamond , \odot and \otimes denote the conjugate, outer product, Khatri Rao, Hadamard and Kronecker products, respectively. \mathbf{I}_N denotes the $N \times N$ identity matrix. The operator $\text{vec}(\cdot)$ vectorizes an $I \times J$ matrix argument, while $\text{unvec}_{I \times J}(\cdot)$ does the opposite operation. Moreover, $\text{vecd}(\cdot)$ forms a vector out of the diagonal of its matrix argument. The n -mode product between a tensor $\mathcal{Y} \in \mathbb{C}^{I \times J \times \dots \times K}$ and a matrix $\mathbf{A} \in \mathbb{C}^{I \times R}$ is denoted as $\mathcal{A} \times_n \mathbf{B}$, for $1 \leq n \leq N$. An identity N -way tensor of dimension $R \times R \times \dots \times R$ is denoted as $\mathcal{I}_{N,R}$. Moreover, $\mathbf{A}_{i\bullet}$ and $\mathbf{A}_{\bullet j}$ denotes the i -th row and j -th column of the matrix \mathbf{A} , respectively. The operator $\lceil x \rceil$ rounds its fractional argument up to the nearest integer. In this paper, we make use of the following identities:

$$(\mathbf{A} \diamond \mathbf{B})^H (\mathbf{C} \diamond \mathbf{D}) = (\mathbf{A}^H \mathbf{C}) \odot (\mathbf{B}^H \mathbf{D}). \quad (1)$$

$$\text{vec}(\mathbf{ABC}) = (\mathbf{C}^T \otimes \mathbf{A}) \text{vec}(\mathbf{B}). \quad (2)$$

$$\text{diag}(\mathbf{a}) \mathbf{b} = \text{diag}(\mathbf{b}) \mathbf{a}. \quad (3)$$

If \mathbf{B} is a diagonal matrix, we have:

$$\text{vec}(\mathbf{ABC}) = (\mathbf{C}^T \diamond \mathbf{A}) \text{vecd}(\mathbf{B}). \quad (4)$$

II. TENSOR PRELIMINARIES

In this section, we provide a brief overview on two tensor decompositions that are of interest to this work, namely the PARAFAC and PARATUCK decompositions. They will be exploited in the formulation of the proposed receivers. In order to keep the presentation concise, the focus is on the

Fig. 1. Transmission time structure.

key definitions and expressions used to represent these two tensor decompositions.

A. PARAFAC decomposition

The PARAFAC decomposition, also known as the canonical polyadic decomposition (CPD), is the most popular tensor decomposition, which expresses a tensor as a sum of a minimum number of rank-one tensors [39]–[42]. For a third-order tensor $\mathcal{X} \in \mathbb{C}^{I \times J \times K}$, its scalar form and frontal slice representation is given as

$$x_{i,j,k} = \sum_{r=1}^R a_{i,r} b_{j,r} c_{k,r}, \quad (5)$$

and

$$\mathbf{X}[k] = \mathbf{A} \mathbf{D}_k(\mathbf{C}) \mathbf{B}^T \in \mathbb{C}^{I \times J}, \quad (6)$$

respectively, where $x_{i,j,k}$ denotes the (i, j, k) -th entry of the tensor $\mathcal{X} \in \mathbb{C}^{I \times J \times K}$ and $\mathbf{X}[k]$ is the k -th frontal slice (a.k.a. as 3-mode slice) of the tensor \mathcal{X} , for $k = 1, \dots, K$. The scalars $a_{i,r}$, $b_{j,r}$ and $c_{k,r}$ are corresponding entries of the three factor matrices \mathbf{A} , \mathbf{B} , and \mathbf{C} , while R denotes the *rank* of the tensor \mathcal{X} . where $\mathbf{X}[k]$ is the k -th frontal slice (a.k.a. as 3-mode slice) of the tensor \mathcal{X} , $k = 1, \dots, K$. The PARAFAC decomposition is powerful due to its essential factor identification uniqueness property, which has its roots on the concept of the Kruskal rank (k-rank). Further details can be found in [43], [44].

B. PARATUCK decomposition

The PARATUCK decomposition [37], [45] is a hybrid tensor decomposition that combines the Tucker [46] and the PARAFAC decompositions. It enjoys the powerful uniqueness properties of the PARAFAC model, while offering a more flexible structure by allowing controlled interactions among its factor matrices. Its scalar form and frontal slice representations are given as

$$x_{i,j,k} = \sum_{r_1=1}^{R_1} \sum_{r_2=2}^{R_2} a_{i,r_1} b_{j,r_2} \omega_{r_1,r_2} c_{k,r_1}^A c_{k,r_2}^B, \quad (7)$$

and

$$\mathbf{X}[k] = \mathbf{A} \mathbf{D}_k(\mathbf{C}^A) \mathbf{\Omega} \mathbf{D}_k(\mathbf{C}^B) \mathbf{B}^T, \quad (8)$$

respectively, where a_{i,r_1} , b_{j,r_2} , ω_{r_1,r_2} , c_{k,r_1}^A and c_{k,r_2}^B are the elements of the matrices $\mathbf{A} \in \mathbb{C}^{I \times R_1}$, $\mathbf{B} \in \mathbb{C}^{J \times R_2}$, $\mathbf{\Omega} \in \mathbb{C}^{R_1 \times R_2}$, $\mathbf{C}^A \in \mathbb{C}^{K \times R_1}$ and $\mathbf{C}^B \in \mathbb{C}^{K \times R_2}$, respectively. \mathbf{A} and \mathbf{B} are referred to as the *factors matrices*, \mathbf{C}^A and \mathbf{C}^B are the *interactions matrices*, while $\mathbf{\Omega}$ is the *core matrix*, whose (r_1, r_2) -th entry defines the level of interaction between the r_1 -th column of \mathbf{A} and the r_2 -th column of \mathbf{B} .

III. SYSTEM MODEL

Let us consider a MIMO communication system assisted by an IRS, where the BS and UT have arrays of M and L antennas, respectively, while the IRS is composed of N elements, which can be individually adjusted/configured to generate phase shifts. We assume a two-stage structured time-domain transmission, as illustrated in Fig. 1, where the estimation time T_E is split into K blocks, and each block has T symbol periods each, with $T_E = KT \leq T_C$. We focus on the uplink scenario, where a multi-antenna UT encodes L independent data streams that are received at the BS with the assistance of an IRS, and possibly reach the BS directly (if the direct link is available).³

In the general case (when the direct link available), the discrete-time baseband received signal vector during the t -th symbol period of the k -th block is given by

$$\mathbf{y}[k, t] = \underbrace{\mathbf{H}^{(D)} \mathbf{x}[k, t]}_{\text{Direct link}} + \underbrace{\mathbf{H} \text{diag}(\mathbf{s}[k, t]) \mathbf{G} \mathbf{x}[k, t]}_{\text{IRS-assisted link}} + \mathbf{b}[k, t], \quad (9)$$

where $\mathbf{H}^{(D)} \in \mathbb{C}^{M \times L}$ is the direct channel matrix between the UT and the BS, whereas $\mathbf{H} \in \mathbb{C}^{M \times N}$ and $\mathbf{G} \in \mathbb{C}^{N \times L}$ denotes the IRS-BS and UT-IRS channel matrices, respectively. The UT employs a space-time encoding scheme that “diagonally” encodes the input symbols such that $\mathbf{x}[k, t] = \text{diag}(\mathbf{w}[k, t]) \mathbf{x}[t] \in \mathbb{C}^{L \times 1}$ contains the encoded symbol vector, $\mathbf{x}[t]$, transmitted during the t -th symbol period of the k -th block. The vector $\mathbf{s}[k, t] \in \mathbb{C}^{N \times 1}$ collects the IRS phase shifts, and $\mathbf{b}[k, t] \in \mathbb{C}^{M \times 1}$ is the corresponding additive white Gaussian noise vector. We assume that the phase shift vector $\mathbf{s} \in \mathbb{C}^{N \times 1}$ and the coding vector $\mathbf{w} \in \mathbb{C}^{L \times 1}$ are constant during the T time slots of the k -th block, and vary from block to block, which means that $\mathbf{s}[k, t] = \mathbf{s}[k]$ and $\mathbf{w}[k, t] = \mathbf{w}[k]$, for $1 \leq t \leq T$.

With these assumptions, collecting the received signals during the T time slots of each block yields

$$\mathbf{Y}[k] = \mathbf{H}^{(D)} \mathbf{D}_k(\mathbf{W}) \mathbf{X}^T + \mathbf{H} \mathbf{D}_k(\mathbf{S}) \mathbf{G} \mathbf{D}_k(\mathbf{W}) \mathbf{X}^T + \mathbf{B}[k], \quad (10)$$

where $\mathbf{Y}[k] \doteq [\mathbf{y}[k, 1], \dots, \mathbf{y}[k, T]] \in \mathbb{C}^{M \times T}$ collects the received signal vectors during the $t = 1, \dots, T$ time slots of the k -th block. In this paper, we consider two possible scenarios. In the first one, the direct link is assumed to be weak, or unavailable. In the second one, both the IRS-assisted link and the direct link are exploited.

Regarding the channel model, no particular assumption is made in this paper. We can assume that the channel matrices follow an i.i.d Rayleigh fading model, or, alternatively, are described by a geometrical model with a few specular paths. For instance, we can assume that the UT-IRS and IRS-BS links are subject to low scattering propagation, such that $\mathbf{H} = \mathbf{A}_{\text{IRS}} \text{diag}(\boldsymbol{\beta}) \mathbf{A}_{\text{BS}}^H$, and $\mathbf{G} = \mathbf{B}_{\text{UT}} \text{diag}(\boldsymbol{\gamma}) \mathbf{B}_{\text{IRS}}^H$, where $\mathbf{A}_{\text{BS}} \in \mathbb{C}^{M \times R_1}$, $\mathbf{A}_{\text{IRS}} \in \mathbb{C}^{N \times R_1}$, $\mathbf{B}_{\text{UT}} \in \mathbb{C}^{L \times R_2}$ and $\mathbf{B}_{\text{IRS}} \in \mathbb{C}^{N \times R_2}$ are the array response matrices, and the vectors $\boldsymbol{\beta}$ and $\boldsymbol{\gamma}$ hold the complex amplitude coefficients of the IRS-BS and UT-IRS

³Although the uplink case is assumed here, the signal model and the algorithms proposed in this paper are equally applicable to the downlink case by just inverting the roles of the transmitter and the receiver.

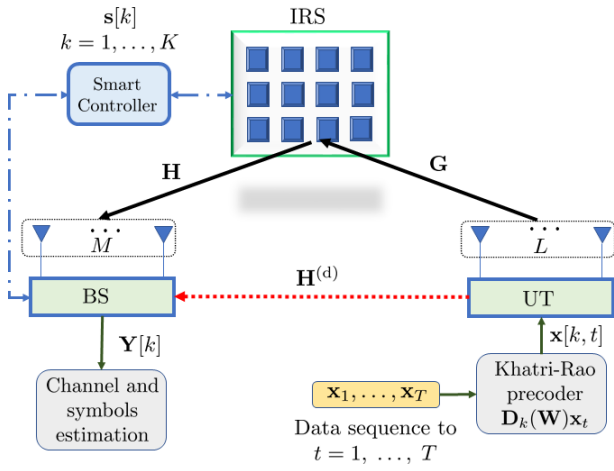

Fig. 2. Uplink IRS-assisted MIMO system diagram.

Fig. 3. Time protocol when the direct BS-UT link is not available.

channels, respectively, while R_1 and R_2 denote the number of clusters between IRS-BS and UT-IRS, respectively [47].

IV. SEMI-BLIND RECEIVER WITHOUT THE DIRECT LINK

Considering the first scenario, when the direct link is weak or unavailable, the received signal in (10) reduces to

$$\mathbf{Y}[k] = \mathbf{H}D_k(\mathbf{S})\mathbf{G}D_k(\mathbf{W})\mathbf{X}^T + \mathbf{B}[k], \quad (11)$$

where $\mathbf{S} \doteq [s[1], \dots, s[K]]^T \in \mathbb{C}^{K \times N}$, $\mathbf{W} \doteq [w[1], \dots, w[K]]^T \in \mathbb{C}^{K \times L}$ are the phase shift matrix and coding matrix, respectively, and $\mathbf{X} \doteq [x[1], \dots, x[T]]^T \in \mathbb{C}^{T \times L}$ is the transmitted symbol matrix. Note that the useful (signal) part of the received signal during the k -th block can be identified as the k -th matrix slice of a *received signal tensor* $\mathcal{Y} \in \mathbb{C}^{M \times T \times K}$ that satisfies a PARATUCK decomposition [36], [37], where the scalar form of the noiseless received signal tensor $\bar{\mathcal{Y}}$ can be expressed as

$$\bar{y}_{m,t,k} = \sum_{n=1}^N \sum_{l=1}^L g_{n,l} x_{t,l} h_{m,n} s_{k,n} w_{k,l}. \quad (12)$$

Note that the interaction matrices of the PARATUCK model correspond to the matrices \mathbf{S} and \mathbf{W} that collect, respectively, the phase shifts (introduced by the IRS) and the coding coefficients (applied at the transmitter), which are fixed and known at the receiver. To summarize, comparing equations (8) and (11), the following correspondence can be established

$$(\mathbf{A}, \mathbf{B}, \mathbf{R}, \mathbf{C}^A, \mathbf{C}^B) \leftrightarrow (\mathbf{H}, \mathbf{X}, \mathbf{G}, \mathbf{S}, \mathbf{W}). \quad (13)$$

The algebraic properties of this PARATUCK tensor signal model will be exploited to formulate our semi-blind receiver for joint channel and symbol estimation. A more complete

scenario, in which the direct link is available, as indicated in (10), will be discussed later.

Remark 1: The IRS-assisted channel is usually represented in an equivalent form in which the channels \mathbf{G} and \mathbf{H} are linked by a Khatri-Rao product. This link can be seen by defining the channel parameter vector $\boldsymbol{\theta} = \text{vec}(\mathbf{G}^T \diamond \mathbf{H})$. In general, $\boldsymbol{\theta}$ can be directly estimated in the LS sense from the received signal, or constructed once the individual estimates of \mathbf{G} and \mathbf{H} are obtained. In this paper, we adopt the second approach.

Our goal is to jointly estimate all the UT-IRS channel $\mathbf{G} \in \mathbb{C}^{N \times L}$, the IRS-BS channel $\mathbf{H} \in \mathbb{C}^{M \times N}$, and the symbol matrix $\mathbf{X} \in \mathbb{C}^{T \times L}$ by exploiting the tensor structure of the received signal model (11). We start by stating the following optimization problem:

$$\min_{\mathbf{H}, \mathbf{G}, \mathbf{X}} \sum_{k=1}^K \left\| \mathbf{Y}[k] - \mathbf{H}D_k(\mathbf{S})\mathbf{G}D_k(\mathbf{W})\mathbf{X}^T \right\|_F. \quad (14)$$

Clearly, this problem is highly nonlinear, since it involves multiple products of the unknown variables, represented by the matrices \mathbf{H} , \mathbf{G} , and \mathbf{X} . However, we take a simpler route to solve the above problem by capitalizing on the multi-linear nature of the received signal and exploiting the PARATUCK tensor model structure [36], [37]. By operating on each one of the three different matrix unfoldings of this tensor model, we derive the key equations for conditionally minimizing the cost function (14) with respect to each unknown matrix in the least squares (LS) sense, while assuming that the remaining quantities are fixed. To simplify the presentation, we temporarily omit the noise term during the development of the main steps.

A. Estimation of the IRS-BS channel

Let us first consider the estimation of the IRS-BS channel matrix. Starting from the frontal slice representation in (11), and stacking column-wise the K matrix slices $\{\mathbf{Y}[k]\}$, $k = 1, \dots, K$, we get

$$\mathbf{Y}_1 \doteq [\mathbf{Y}[1], \dots, \mathbf{Y}[K]] = \mathbf{H}\mathbf{F}^T + \mathbf{B}_1 \in \mathbb{C}^{M \times TK}, \quad (15)$$

which corresponds to the 1-mode unfolding of the received signal tensor in (12), where

$$\mathbf{F} \doteq \begin{bmatrix} \mathbf{X}D_1(\mathbf{W})\mathbf{G}^TD_1(\mathbf{S}) \\ \vdots \\ \mathbf{X}D_K(\mathbf{W})\mathbf{G}^TD_K(\mathbf{S}) \end{bmatrix} \in \mathbb{C}^{TK \times N}, \quad (16)$$

and \mathbf{B}_1 is the corresponding 1-mode unfolding of the additive noise tensor. The estimation of \mathbf{H} can be obtained by solving the following LS problem

$$\hat{\mathbf{H}} = \arg \min_{\mathbf{H}} \left\| \mathbf{Y}_1 - \mathbf{H}\mathbf{F}^T \right\|_F^2, \quad (17)$$

the solution of which is given by

$$\hat{\mathbf{H}} = \mathbf{Y}_1 (\mathbf{F}^T)^\dagger. \quad (18)$$

B. UT-IRS channel estimation

To derive the update equation for the estimation of the UT-IRS channel matrix \mathbf{G} , let us apply the $\text{vec}(\cdot)$ operator to (11), which gives

$$\begin{aligned} \text{vec}(\mathbf{Y}[k]) &= (\mathbf{X} \otimes \mathbf{H})\text{vec}(D_k(\mathbf{S})\mathbf{G}D_k(\mathbf{W})) \\ &= (\mathbf{X} \otimes \mathbf{H})(D_k(\mathbf{W}) \otimes D_k(\mathbf{S}))\text{vec}(\mathbf{G}) + \text{vec}(\mathbf{B}[k]), \end{aligned} \quad (19)$$

where we have applied property (2) twice. Now, applying property (3) to (19) yields

$$\text{vec}(\mathbf{Y}[k]) = (\mathbf{X} \otimes \mathbf{H})\text{diag}(\text{vec}(\mathbf{G})) (\mathbf{W}_{k\bullet}^T \otimes \mathbf{S}_{k\bullet}^T) + \text{vec}(\mathbf{B}[k]), \quad (20)$$

where we have used the fact that $(D_k(\mathbf{W}) \otimes D_k(\mathbf{S}))$ is actually $\text{diag}(\mathbf{W}_{k\bullet}^T \otimes \mathbf{S}_{k\bullet}^T)$. By stacking column-wise $\text{vec}(\mathbf{Y}[1]), \dots, \text{vec}(\mathbf{Y}[K])$, and using (20), we can obtain the 3-mode unfolding of the received signal tensor as follows

$$\begin{aligned} \mathbf{Y}_3 &\doteq [\text{vec}(\mathbf{Y}[1]), \dots, \text{vec}(\mathbf{Y}[K])] \\ &= (\mathbf{X} \otimes \mathbf{H})\text{diag}(\text{vec}(\mathbf{G}))\boldsymbol{\Psi} + \mathbf{B}_3, \in \mathbb{C}^{TM \times K} \end{aligned} \quad (21)$$

where

$$\begin{aligned} \boldsymbol{\Psi} &\doteq [\mathbf{W}_{1\bullet}^T \otimes \mathbf{S}_{1\bullet}^T, \dots, \mathbf{W}_{K\bullet}^T \otimes \mathbf{S}_{K\bullet}^T] \\ &= \mathbf{W}^T \diamond \mathbf{S}^T \in \mathbb{C}^{LN \times K}. \end{aligned} \quad (22)$$

Finally, vectorizing (21) and applying property (2) yields

$$\text{vec}(\mathbf{Y}_3) = [\boldsymbol{\Psi}^T \diamond (\mathbf{X} \otimes \mathbf{H})] \text{vec}(\mathbf{G}) + \text{vec}(\mathbf{B}_3). \quad (23)$$

Thus, an estimate of \mathbf{G} in the LS sense can be obtained by solving the following problem

$$\hat{\mathbf{G}} = \arg \min_{\mathbf{G}} \left\| \text{vec}(\mathbf{Y}_3) - [\boldsymbol{\Psi}^T \diamond (\mathbf{X} \otimes \mathbf{H})]^\dagger \text{vec}(\mathbf{G}) \right\|_F^2, \quad (24)$$

the solution of which is given by

$$\hat{\mathbf{G}} = \text{unvec}_{N \times L} \left([\boldsymbol{\Psi}^T \diamond (\mathbf{X} \otimes \mathbf{H})]^\dagger \text{vec}(\mathbf{Y}_3) \right). \quad (25)$$

Remark 2: The step 2 of Algorithm 1, which is concerned with the estimation of the UT-IRS channel matrix, can be simplified by assuming that $\boldsymbol{\Psi}$ defined in (22) is an $LN \times K$ semi-unitary matrix satisfying $\boldsymbol{\Psi}^* \boldsymbol{\Psi}^T = K \mathbf{I}_{LN}$ (this choice is discussed in Appendix B). In this case, it can be shown that the LS estimation step (25) simplifies to

$$\text{vec}(\mathbf{G}) = (1/K) \cdot \boldsymbol{\Sigma}_{\mathbf{Q}}^{-1} (\boldsymbol{\Psi}^T \diamond \mathbf{Q})^H \text{vec}(\mathbf{Y}_3), \quad (26)$$

where $\mathbf{Q} \doteq [\mathbf{q}_1, \dots, \mathbf{q}_{LN}] = \mathbf{X} \otimes \mathbf{H} \in \mathbb{C}^{TM \times LN}$, and

$$\boldsymbol{\Sigma}_{\mathbf{Q}} \doteq \begin{bmatrix} \|\mathbf{q}_1\|^2 & & \\ & \ddots & \\ & & \|\mathbf{q}_{LN}\|^2 \end{bmatrix}. \quad (27)$$

In addition to the complexity reduction, our numerical experiments have shown that the semi-unitary design for $\boldsymbol{\Psi}$ also improves the convergence speed of Algorithm 1. On the other hand, this condition requires $K \geq LN$. It is worth noting, however, that although advantageous from a performance/complexity viewpoint, the semi-unitary condition is not necessary.

C. Symbol estimation

The final step of our semi-blind receiver estimates the transmitted symbol matrix. To this end, we start from (11), and stack column-wise the matrix slices $\mathbf{Y}[1], \dots, \mathbf{Y}[K]$, to get

$$\mathbf{Y}_2 \doteq [\mathbf{Y}[1]^T, \dots, \mathbf{Y}[K]^T] = \mathbf{X} \mathbf{E}^T \in \mathbb{C}^{T \times MK}, \quad (28)$$

which corresponds to the 2-mode unfolding of the received signal tensor in (12), where

$$\mathbf{E} \doteq \begin{bmatrix} \mathbf{H}D_1(\mathbf{S})\mathbf{G}D_1(\mathbf{W}) \\ \vdots \\ \mathbf{H}D_K(\mathbf{S})\mathbf{G}D_K(\mathbf{W}) \end{bmatrix} \in \mathbb{C}^{MK \times L}. \quad (29)$$

Adding the noise term, we have $\mathbf{Y}_2 = \mathbf{X} \mathbf{E}^T + \mathbf{B}_2$. The LS estimate of \mathbf{X} is then obtained by solving

$$\hat{\mathbf{X}} = \arg \min_{\mathbf{X}} \|\mathbf{Y}_2 - \mathbf{X} \mathbf{E}^T\|_F^2, \quad (30)$$

the solution of which is given by

$$\hat{\mathbf{X}} = \mathbf{Y}_2 (\mathbf{E}^T)^\dagger. \quad (31)$$

The proposed semi-blind receiver makes use of (18), (26) and (31) to obtain the estimates of channel matrices \mathbf{G} and \mathbf{H} , and the symbol \mathbf{X} via a trilinear alternating least squares based estimation scheme, herein referred to as TALS receiver. More specifically, the algorithm consists of a three-step estimation procedure that estimates one matrix at each step, while fixing the other two matrices to their values obtained at the previous estimation steps. Note that the proposed TALS receiver is a semi-blind method, since no training sequences are required. The receiver algorithm is summarized in Algorithm 1.

The stopping criterion relies on the normalized squared error measure computed at the end of the i -th iteration,

given by $\epsilon_{(i)} = \sum_{k=1}^K \|\mathbf{Y}[k] - \hat{\mathbf{Y}}[k]_{(i)}\|_F^2 / \|\mathbf{Y}[k]\|_F^2$, where $\hat{\mathbf{Y}}[k]_{(i)} = \hat{\mathbf{H}}_{(i)} \mathbf{D}_k(\mathbf{S}) \hat{\mathbf{G}}_{(i)} \mathbf{D}_k(\mathbf{W}) \hat{\mathbf{X}}_{(i)}^T$. The convergence is declared when the difference between the reconstruction errors of two successive iterations falls below a threshold, i.e., $|\epsilon_{(i)} - \epsilon_{(i-1)}| \leq \delta$. In this work, we assume $\delta = 10^{-5}$. The convergence criterion of TALS is based on the difference between the reconstruction errors computed in two successive iterations. The complexity of the TALS receiver is dominated by the matrix inverses in steps 1 and 3, which have complexity orders $\mathcal{O}(TKN^2)$ and $\mathcal{O}(LKM^2)$, respectively [35]. Considering the complexity of step 2, which only involves matrix products, the total complexity by iteration of the TALS receiver is given by $\mathcal{O}(TKN^2[1+M^2L] + KLM[NT+M])$.

D. Identifiability

The joint recovery of \mathbf{H} , \mathbf{G} , and \mathbf{X} requires that the three LS problems in (17), (24), and (30), have unique solutions, respectively. More specifically, the uniqueness of \mathbf{H} requires that \mathbf{F} defined in (16) have full column-rank, which implies $TK \geq N$, while the uniqueness of \mathbf{G} requires that $[\Psi^T \diamond (\mathbf{X} \otimes \mathbf{H})]$ have full column-rank, implying $TKM \geq LN$. Likewise, the uniqueness of \mathbf{X} requires that \mathbf{E} defined in (29) be of full column-rank, which implies $MK \geq L$. Note that the number K of transmitted blocks is the common parameter in these three conditions, which must be simultaneously satisfied. In summary, the following conditions must be simultaneously satisfied the joint uniqueness of \mathbf{H} , \mathbf{G} , and \mathbf{X} :

$$TK \geq N, \quad TKM \geq LN, \quad MK \geq L. \quad (32)$$

These conditions establish useful trade-offs involving the time diversities (parameters K and T) and spatial diversities (parameters N , M , L) for the joint recovery of the channel and symbol matrices. More specifically, reducing the number of blocks K and/or the number of symbol periods T can be compensated by a corresponding increase on the number of BS antennas M . As a special case, if the number of BS antennas exceeds the number of UT antennas ($M \geq L$), satisfying these conditions reduces to $TK \geq N$.

Under the conditions stated above, the estimates of \mathbf{G} , \mathbf{H} , and \mathbf{X} delivered by Algorithm 1 are affected by scaling ambiguities that compensate each other, as follows

$$\hat{\mathbf{H}} \mathbf{\Delta}_H = \mathbf{H}, \quad \hat{\mathbf{X}} \mathbf{\Delta}_X = \mathbf{X}, \quad \mathbf{\Delta}_H^{-1} \hat{\mathbf{G}} \mathbf{\Delta}_X^{-1} = \mathbf{G}, \quad (33)$$

where $\mathbf{\Delta}_G$, $\mathbf{\Delta}_H$, and $\mathbf{\Delta}_X$ are diagonal matrices. These scaling ambiguities can be handled by assuming that the first row of the symbol matrix $\mathbf{X}_{1 \bullet} \in \mathbb{C}^{1 \times L}$ contains identification symbols that are known at the receiver. Note that the columns of $\mathbf{X} \in \mathbb{C}^{T \times L}$ correspond to the L data streams that are spatially multiplexed at the transmitter. Hence, the knowledge of the first row of $\mathbf{X} \in \mathbb{C}^{T \times L}$ means that the first symbol of each data stream is a known pilot. Therefore, the knowledge of L pilots allows us to eliminate the scaling ambiguity by normalization. A simple choice is to assume that $\mathbf{X}_{1 \bullet} = [1, 1, \dots, 1]$, so that $\mathbf{\Delta}_X$ can be determined from the first row of the estimated symbol matrix $\hat{\mathbf{X}}$ after convergence of Algorithm 1, and cancelled out by normalization.

Fig. 4. Time protocol when the assisted link via IRS link is activated.

Remark 3: The identifiability conditions (32) show that the minimum value of K can be small if the block length T is large. However, this minimum value may not be enough to obtain a fine CE estimate, especially when the number of IRS elements is large. In this case, K must be increased to ensure a good performance. To overcome this practical challenge, we can resort to alternative strategies proposed in the literature, such as the partitioning of the IRS panel into multiple sub-panels [26], [48]. As an example, for an IRS consisting of $N = 100$ elements and partitioned into 10 sub-panels, the minimum value of K that ensures identifiability according to (32) is reduced by a factor of 10, for fixed values of L and M , leading to an increased spectral efficiency. In this case, the proposed semi-blind receiver is run independently and in parallel for each sub-panel. Moreover, if the elements within a given sub-panel are spatially correlated, one can assume the same phase shift for the entire sub-panel and further reduce K . Consequently, each sub-panel is associated with one aggregated channel coefficient (see, e.g. [10]) for further details on this strategy.

V. DIRECT LINK AIDED SEMI-BLIND RECEIVER

In this section, we present an enhanced version of the semi-blind receiver derived in the previous section that exploits the direct link between UT and BS, whenever it is available. The idea is to dedicate part of the transmission time resources to the direct link, so that an initial estimate of the transmitted symbols and direct channel can be obtained. The initial symbol estimates are exploited as a “warm start” of the TALS algorithm for estimating the UT-IRS and IRS-BS channels, while refining the estimates of the symbols and the direct channel. To this end, we slightly modify the transmission protocol by splitting the total transmission time of K blocks into two time windows of duration $T_1 = K_1T$ and $T_2 = K_2T$ symbol periods, respectively, where $K = K_1 + K_2$ is the total number of time blocks, and $T_c = T_1 + T_2$ the total transmission duration. The time protocol is depicted in Figure 4. During the first time window, the UE transmits data using a coding matrix $\mathbf{W}_1 \in \mathbb{C}^{K_1 \times L}$, while in the second time window it uses the coding matrix $\mathbf{W}_2 \in \mathbb{C}^{K_2 \times L}$ and the phase shift matrix $\mathbf{S} \in \mathbb{C}^{K_2 \times N}$. A short discussion on the design of \mathbf{W}_2 and \mathbf{S} is provided in the Appendix B.

The receiver processing has two stages. In the first one, a joint estimation of the direct channel and the transmitted symbols is carried out during the first time window by exploiting the PARAFAC tensor model of the received signals. The second stage makes use of the estimated symbols in the first time window as an initialization of the TALS algorithm that jointly estimates the involved channel matrices, while refining the symbol estimates during its iterative process. As will be

shown later in our numerical experiments, the initialization of the IRS-assisted link using the direct link estimates yields an enhanced TALS algorithm with accelerated convergence and improved estimation accuracy. Therefore, in stage one the IRS is “off”, following the approach of [14], so that the received signal at BS is given as

$$\mathbf{Y}^{(D)}[k_1] = \mathbf{H}^{(D)}D_{k_1}(\mathbf{W}_1)\mathbf{X}^T + \mathbf{B}[k_1], \quad (34)$$

for $k_1 = 1, \dots, K_1$, where $\mathbf{W}_1 \in \mathbb{C}^{K_1 \times L}$ is the coding matrix used during the first time window of K_1 blocks. The signal part of (34) can be viewed as the k_1 -th frontal matrix slice of a three-way tensor $\overline{\mathbf{Y}}^{(D)} \in \mathbb{C}^{M \times T \times K_1}$ that follows a PARAFAC decomposition with factor matrices $\mathbf{H}^{(D)}$, \mathbf{X} , \mathbf{W}_1 . By analogy with (6), the following correspondences can be deduced:

$$(\mathbf{A}, \mathbf{B}, \mathbf{C}) \leftrightarrow (\mathbf{H}^{(D)}, \mathbf{X}, \mathbf{W}_1). \quad (35)$$

From the uniqueness property of the PARAFAC model [43], [44], one can obtain a useful condition for guaranteed direct channel and symbol recovery in the general case where all the factor matrices are unknown. In our context, however, since the coding matrix \mathbf{W}_1 is assumed to be known at the receiver (BS), simplified conditions can be obtained. Since \mathbf{W}_1 has full column-rank (which requires $K_1 \geq L$), $M \geq 2$ receive antennas and $T \geq 2$ time slots are enough for the joint recovery of $\mathbf{H}^{(D)}$ and \mathbf{X} . This problem can be efficiently solved by means of the Khatri-Rao Factorization algorithm [25], as will be detailed next.

A. Stage I: Joint direct channel and symbol estimation

Starting from (34), and defining

$$\mathbf{Y}^{(D)} \doteq [\text{vec}(\mathbf{Y}^{(D)}[1]), \dots, \text{vec}(\mathbf{Y}^{(D)}[K_1])] \in \mathbb{C}^{MT \times K_1}, \quad (36)$$

that collects the signals received during the first K_1 time blocks, we have

$$\mathbf{Y}^{(D)} = (\mathbf{X} \diamond \mathbf{H}^{(D)})\mathbf{W}_1^T + \mathbf{B}, \quad (37)$$

where we have used property (4), and $\mathbf{B} = [\text{vec}(\mathbf{B}[1]), \dots, \text{vec}(\mathbf{B}[K_1])] \in \mathbb{C}^{MT \times K_1}$ is the corresponding noise matrix. Defining

$$\mathbf{Z} \doteq (1/K_1)\mathbf{Y}^{(D)}\mathbf{W}_1^* = \mathbf{X} \diamond \mathbf{H}^{(D)} + (1/K_1)\mathbf{B}\mathbf{W}_1^*,$$

an estimate of \mathbf{X} and $\mathbf{H}^{(D)}$ can be found using the Khatri-Rao Factorization algorithm that solves the following problem [49], [50]

$$\min_{\mathbf{X}, \mathbf{H}^{(D)}} \|\mathbf{Z} - \mathbf{X} \diamond \mathbf{H}^{(D)}\|_F, \quad (38)$$

which is equivalent to solving L rank-1 matrix approximation subproblems, and can be stated as

$$(\hat{\mathbf{X}}, \hat{\mathbf{H}}^{(D)}) = \arg \min_{\{\mathbf{x}_l\}, \{\mathbf{h}_l^{(D)}\}} \sum_{l=1}^L \left\| \tilde{\mathbf{Z}}_l - \mathbf{h}_l^{(D)} \mathbf{x}_l^T \right\|_F, \quad (39)$$

where $\tilde{\mathbf{Z}}_l \doteq \text{unvec}_{M \times T}(\mathbf{z}_l) \in \mathbb{C}^{M \times T}$, and $\mathbf{z}_l \in \mathbb{C}^{MT \times 1}$ denotes the l -th column of \mathbf{Z} , while $\mathbf{h}_l^{(D)} \in \mathbb{C}^{M \times 1}$ and $\mathbf{x}_l^T \in \mathbb{C}^{1 \times T}$ are the l -th column of $\mathbf{H}^{(D)}$ and l -th row of \mathbf{X} ,

respectively. Due to space limitations, we have suppressed the details of the KRF algorithm. A pseudo code of this algorithm can be found in [25].

Remark 4: As an alternative to the KRF algorithm, one can also resort to the bilinear alternating least squares (BALS) algorithm that jointly estimates the direct channel matrix and the symbol matrix in an alternating way. In this work, we advocate using the KRF algorithm since it provides similar performance to BALS, while being a closed-form solution that affords an efficient implementation, since the N involved rank-one matrix approximations can be optimized if executed in a parallel processing hardware.

B. Stage II: IRS-assisted channel estimation and symbol refinement

After the stage I, the IRS is turned “on” during the second transmission time window that spans K_2 blocks. In this case, the total received signal is given by the sum of the direct link and IRS-assisted contributions, and is given by

$$\begin{aligned} \mathbf{Y}[k_2] &= \mathbf{H}^{(D)}D_{k_2}(\mathbf{W}_2)\mathbf{X}^T \\ &+ \mathbf{H}D_{k_2}(\mathbf{S})\mathbf{G}D_{k_2}(\mathbf{W}_2)\mathbf{X}^T + \mathbf{B}[k_2]. \end{aligned} \quad (40)$$

From the estimated symbol and direct channel matrices $\hat{\mathbf{X}}$ and $\hat{\mathbf{H}}^{(D)}$ delivered by the KRF algorithm in stage I (c.f. problem (39)), the interference from the direct link can be removed (or minimized) by subtracting an estimate of its contribution from the total received signal in stage II, yielding

$$\mathbf{Q}[k_2] = \mathbf{Y}[k_2] - \hat{\mathbf{H}}^{(D)}D_{k_2}(\mathbf{W}_2)\hat{\mathbf{X}}^T. \quad (41)$$

From (40), we can write (41) as

$$\mathbf{Q}[k_2] = \mathbf{H}D_{k_2}(\mathbf{S})\mathbf{G}D_{k_2}(\mathbf{W}_2)\mathbf{X}^T + \overline{\mathbf{B}}[k_2], \quad (42)$$

where $\overline{\mathbf{B}}[k_2] = \mathbf{B}[k_2] + \mathbf{E}_H D_{k_2}(\mathbf{W}_2)\mathbf{E}_X^T$ is the effective noise, while $\mathbf{E}_H \doteq \mathbf{H}^{(D)} - \hat{\mathbf{H}}^{(D)}$ and $\mathbf{E}_X \doteq \mathbf{X} - \hat{\mathbf{X}}$ are error matrices associated with the estimates of the direct channel and symbol matrix in stage I. It is clear that the energy of the overall additive noise term in (41) will depend on the energy of these error terms, which in turn depends on the quality of the direct link compared with the IRS-assisted link.

Note that the signal part of (42) corresponds to a PARATUCK decomposition of $\mathbf{Q} \in \mathbb{C}^{M \times T \times K_2}$, which is analogous to the (11), where the third mode has dimension K_2 (instead of K). Hence, estimates of the IRS-assisted channel matrices \mathbf{G} and \mathbf{H} , as well as refined estimates of the symbol matrix \mathbf{X} can be obtained from \mathbf{Q} by following the procedure discussed in Section IV.A-IV.C. This leads to a second semi-blind receiver, referred to as *enhanced* TALS (E-TALS), summarized in Algorithm 2.

In addition, from the refined symbol estimates, an enhanced estimate of the direct channel matrix $\mathbf{H}^{(D)}$ can also be obtained at the end of stage II, i.e., at the convergence of the algorithm. More specifically, suppose that the E-TALS algorithm has converged at the i -th iteration, and let $\mathbf{X}_{(i)}$ be the refined estimate of the symbol matrix obtained at this iteration. Substituting $\hat{\mathbf{X}}_{(i)}$ into (34), a refined estimate of the direct channel can be obtained by solving the following problem

$$\min_{\mathbf{H}^{(D)}} \sum_{k_1=1}^{K_1} \left\| \mathbf{Y}^{(D)}[k_1] - \mathbf{H}^{(D)}D_{k_1}(\mathbf{W}_1)\hat{\mathbf{X}}_{(i)}^T \right\|_F, \quad (43)$$

the solution of which is given by

$$\hat{\mathbf{H}}^{(D)} = [\mathbf{Y}^{(D)}[1], \dots, \mathbf{Y}^{(D)}[K_1]] [(\mathbf{W}_1 \diamond \hat{\mathbf{X}}_{(i)})^T]^\dagger. \quad (44)$$

In summary, when the direct link is available, the proposed E-TALS receiver allows not only to improve the convergence speed of stage II by using previous symbol estimates as a “warm start”, but also allows to continuously improve the accuracy of these symbol estimates *via* the IRS-assisted link, while enhancing the estimate of the involved channel matrices, including the direct channel matrix. As will be clear from our numerical experiments, the availability of the direct link makes E-TALS (Algorithm 2) advantageous compared to TALS without the availability of the direct link (Algorithm 1).

Note that the identifiability condition discuss to TASL it is valid for E-TALS algorithm 2 with an additional restriction, which consist in $K_1 \geq L$ is required due the proposed KRF solution in first stage.

 - (b) Compute a refined symbol estimate $\hat{\mathbf{X}}_{(i)}$ from step 3 of Algorithm 1.
 4. Repeat steps 2 and 3 until convergence.
 5. From the refined estimate $\hat{\mathbf{X}}_{(i)}$, compute a final estimate of the direct link channel: $\hat{\mathbf{H}}^{(D)} = [\mathbf{Y}^{(D)}[1], \dots, \mathbf{Y}^{(D)}[K_1]] [(\mathbf{W}_1 \diamond \hat{\mathbf{X}}_{(i)})^T]^\dagger.$
-

VI. NUMERICAL RESULTS

We evaluate the performance of the proposed semi-blind receivers. The CE accuracy is evaluated in terms of the normalized mean square error (NMSE) given by

$$\text{NMSE}(\hat{\mathbf{\Pi}}) = \frac{1}{R} \sum_{r=1}^R \frac{\|\mathbf{\Pi}^{(r)} - \hat{\mathbf{\Pi}}^{(r)}\|_F^2}{\|\mathbf{\Pi}^{(r)}\|_F^2}, \quad (45)$$

where $\mathbf{\Pi} = \mathbf{H}, \mathbf{G}$ and $\hat{\mathbf{\Pi}}^{(r)}$ denotes the estimation of the channels at the r -th run, and R denotes the number of Monte-Carlo runs. The same definition applies to the estimated UT-IRS channel. We also evaluate the symbol error rate (SER) performance as a function of the signal to noise ratio (SNR) defined as $\text{SNR} = 10 \log_{10} (\|\mathcal{Y}\|_F^2 / \|\mathcal{B}\|_F^2)$, where \mathcal{Y} is the noiseless received signal tensor generated according (12), and \mathcal{B} is the additive noise tensor. All the results represent an

average from at least $R = 3000$ Monte Carlo runs. Each run corresponds to an independent realization of the channel matrices, transmitted symbols and noise term. Regarding the channel model, we consider the Rayleigh fading case (i.e. the entries of channel matrices are independent and identically distributed zero-mean circularly-symmetric complex Gaussian random variables) as well as the geometrical channel model with a few specular paths, as described in Section II. We assume uniform linear arrays at the BS and UT, while the IRS panel has a uniform rectangular array structure. The transmitted symbols follow a 16-PSK constellation. When considering the direct link, we define α as the effective SNR gap (in dB) between direct link and the IRS-assisted link. Otherwise stated, the average received signal power for the direct link is α dB smaller than that of the IRS-assisted link. In Figures 5-7, we assume that the direct link is blocked and focus on the TALS receiver (Algorithm 1), while in the remaining figures the direct link is available and both TALS and E-TALS are considered.

A. TALS performance: NMSE, CRB and SER

In Figure 5, we evaluate the NMSE performance of the semi-blind TALS receiver, while comparing it with competing CE methods. We consider as references for comparisons the Block-LS⁴ CE method of [23] and the pilot-assisted PARAFAC-BALS method proposed in [25]. Both methods are direct competitors since they operate on the same system model as the proposed semi-blind receiver. The second is based on an iterative estimation of the UT-IRS and IRS-BS channel matrices using a BALS algorithm. However, the main difference is on the fact that these methods require the transmission of pilot sequences, while the proposed receiver jointly estimate the channel and the transmitted symbols semi-blindly. In this experiment, we assume $M = 5$ antennas at the BS, $L = 2$ antennas at the UT, and an IRS composed of $N = 64$ reflecting elements. The total transmission time consists of $K = 128$ blocks of $T = 5$ time slots each. The channel matrices associated with the IRS-BS and UT-IRS are generated according to a geometrical channel model, assuming a single path scenario (line of sight case). The path directions are randomly generated according to a uniform distribution. At each Monte Carlo run, the azimuth and elevation angles are drawn within the intervals $[-\pi/2, \pi/2]$ and $[0, \pi/2]$, respectively.

As it can be seen from the figure, the TALS receiver offers a more accurate overall channel estimate than Block-LS and PAFAC-BALS. In particular, the Block-LS method has an SNR gap of approximately 5dB compared to TALS. Indeed, the TALS receiver fully exploits the trilinear structure of the received signal, and its improved performance comes from the data-aided nature of the receiver, where the symbol estimates

⁴The competing CE method of [23] has two stages. In the first one, the cascaded channel $\mathbf{C}_k = \mathbf{G}D_k(\mathbf{S})\mathbf{H}$ associated with each time block k is individually estimated via an LS method, while in the second stage the path angles are extracted from the unstructured channel estimates. Since our semi-blind receiver is not concerned with the extraction of the angular parameters of the channel matrices (which can be done using existing methods), we compare the proposed TALS method with the first stage of the Block-LS method of [23].

Fig. 5. NMSE performance of TALS in comparison with competing methods.

 Fig. 6. Comparison with the CRB for the estimation of \mathbf{H} and \mathbf{G} .

are used to further improve the channel estimates during the iterative process. On the other hand, we should point out that the TALS receiver is more complex than PARAFAC-BALS and Block-LS due to the additional symbol estimation step at every iteration.

In Figure 6, we compare the NMSE performance of the individual channel matrices \mathbf{H} and \mathbf{G} with their corresponding CRB references (more details given in Appendix B). Note that the NMSE curves decrease linearly with the SNR, presenting a constant gap with respect to their CRB references regardless of the SNR value. In particular, note that the estimate of \mathbf{G} is closer to its CRB than is the estimate of \mathbf{H} . Figure 7 depicts the symbol error rate for some values of N and $T = 2$. The other parameters follow the same setup as in Figures 5 and 6. Note that the SER performance degrades with an increasing N . This result is comprehensive, since more IRS elements implies more channel coefficients to be estimated while the training time window is fixed.

B. E-TALS performance: NMSE, complexity and SER

In Figure 8, we reduce the training time such that the row-orthonormal semi-unitary design of matrix Ψ is not satisfied. For this case, we consider a geometric channel model. In addition, the number of training blocks is equal to $K = 80$, each of them composed of $T = 5$ time slots. The remaining system parameters are $L = 2$, $M = 5$, $L_h = 3$, $L_g = 2$, and 3000 Monte Carlos runs. For the E-TALS algorithm, the

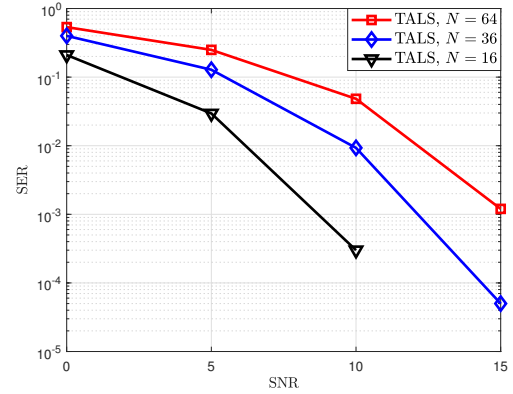

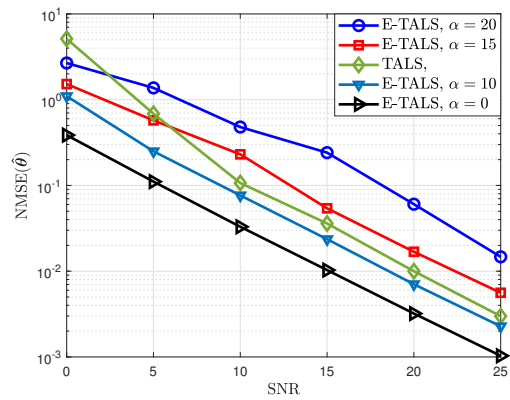

Fig. 7. SER performance of the TALS algorithm.

 Fig. 8. Channel estimation performance (non-orthogonal Ψ).

 Fig. 9. NMSE performance of E-TALS for different values of α , and the impact of symbol refinements.

splitting of the training time resources is such that $K_1 = 16$ and $K_2 = 64$. In this experiment, we consider that step 3(b) is “off”, which means that the estimate of the symbol matrix $\hat{\mathbf{X}}$ delivered by the stage I of the receiver is fixed during the stage II. The results show that the presence of the direct link can be efficiently exploited by the E-TALS receiver to further improve the accuracy of the channel estimate. In particular, we can note a performance gain of E-TALS over TALS for $\alpha = 0$ and $\alpha = 10$.

In Figures 9, 10 and 11, we present how the refine-

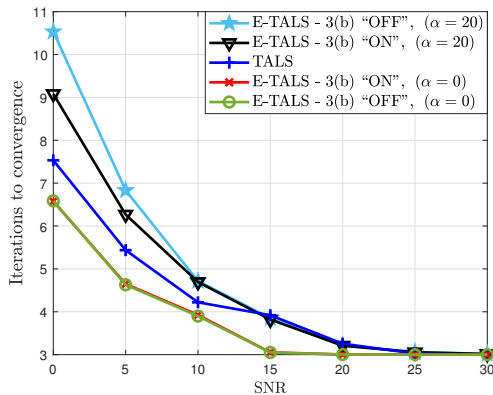

Fig. 10. Convergence (number of iterations) as a function of the SNR.

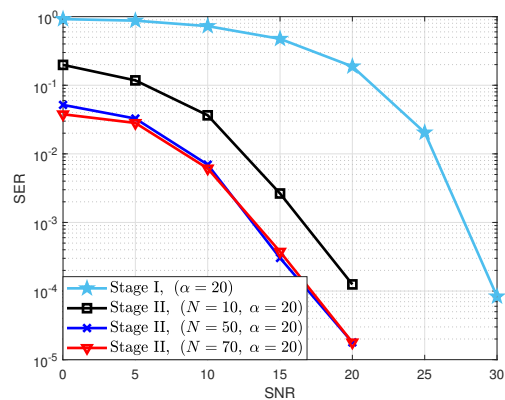

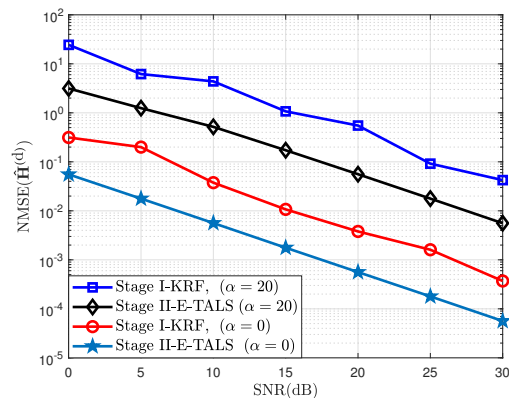

Fig. 11. Computation time of TALS and E-TALS for different settings.

ment step in algorithm E-TALS affects the CE performance. Assuming the parameter set $\{N, M, L, T, K_1, K_2\} = \{70, 10, 2, 5, 10, 140\}$, we consider two cases: (1) the direct and the IRS-assisted links have the same power ($\alpha = 0$), and (2) the direct link is 20dB weaker than the IRS-assisted link ($\alpha = 20$). Let us first consider the case 1. In this case, the result depicted in 9 shows that E-TALS and TALS present a very close NMSE performance, indicating that the impact of the refinement of the symbol estimates in the performance is negligible. Although a performance gain is not obtained, as shown in Figure 10, the E-TALS algorithm needs fewer iterations to converge in comparison to TALS. Furthermore, we can see in Figure 11 that turning “off” step 3(b) of E-TALS results in a reduced average computation time. we can observe a significant impact on the CE. Considering now the case 2 ($\alpha = 20$ dB), we can see that TALS becomes the preferred option. This result is aligned with those of Figure 8, showing that E-TALS is advantageous when the direct link is not too weak, as expected.

Figure 12 depicts the SER performance of E-TALS, assuming $\alpha = 20$, $M = 10$, $T = 5$. The number of time blocks is $K = 150$, where $K_1 = 10$ blocks are allocated to stage I and $K_2 = 140$ blocks to stage II. We can clearly see that the SER associated with the refined symbol estimates provided by stage II is significantly lower than that delivered by stage I (KRF), corroborating the enhancement provided by the joint channel and symbol estimation in stage II of E-TALS. In particular, the SER is further improved as N is

 Fig. 12. SER performance of E-TALS algorithm for different values of N .

 Fig. 13. NMSE of the $\mathbf{H}^{(d)}$ for E-TALS.

increased from 10 to 50. In Figure 13, we highlight the benefit of the symbol refinements provided by stage II of E-TALS to further improve the estimate of the direct channel $\mathbf{H}^{(d)}$ delivered by stage I. The system parameters are $N = 50$, $M = 10$, $L = 2$, $T = 5$ and $K_1 = 10$. Recall that step 5 of the E-TALS algorithm makes use of the refined symbol estimates $\hat{\mathbf{X}}$ to obtain a final LS estimate of the direct channel as $\hat{\mathbf{H}}^{(D)} = [\mathbf{Y}^{(D)}[1], \dots, \mathbf{Y}^{(D)}[K_1]] [(\mathbf{W}_1 \diamond \hat{\mathbf{X}}_{(i)})^T]^\dagger$. We can see that stage II of E-TALS provides an enhanced estimate of the direct channel compared to stage I, for both $\alpha = 0$ or $\alpha = 20$. This result confirms that the refinement of the symbol estimates obtained via the IRS-assisted link is also beneficial to further improves the accuracy of the estimate of the direct channel, while providing estimates of the IRS-assisted channels.

In Figure 14, we evaluate the impact of the design of Ψ on the performance of the proposed semi-blind receiver. As it can be seen from these results, the proposed joint orthogonal design enhances the channel and symbol estimation performances. Moreover, this orthogonal design allows to reduce the overall computational cost of the semi-blind receiver, since fewer iterations are required for convergence.

VII. CONCLUSION

In this paper, we have proposed a novel tensor-based semi-blind receiver design for IRS-assisted MIMO communication systems that exploits PARATUCK tensor model for the re-

 Fig. 14. Orthogonal versus non-orthogonal designs for Ψ .

ceived signals. The proposed semi-blind receiver is a data-aided channel estimator that avoids the use of pilot sequences, while performing a joint estimation of the IRS-BS channel, UT-IRS channel, and the transmitted symbols in an iterative way by means of a TALS (algorithm 1) when the direct link is unavailable or negligible or by means of E-TALS (algorithm 2) if the direct link is available. We have studied the design of the coding matrix and IRS phase shift matrix, and a joint design has been proposed that optimizes the receiver performance while simplifying the CRB derivations. Our results also indicate that the TALS receiver yields an improved CE accuracy than “block-LS” and BALS algorithms, while offering a joint channel and symbol recovery, thus being a good solution for IRS-assisted MIMO systems, especially when pilot resources are limited or not available. Analytical expressions for the CRB have been derived for the proposed semi-blind receiver. We believe that extending the proposed semi-blind receiver to the multiuser scenario, in the presence of frequency-selective channels is an important topic for future research. The generalization of the proposed approach to the multi-IRS case is also an interesting topic for future work.

APPENDIX A EXPECTED CRAMÉR RAO LOWER BOUND

The CRB is the lowest estimation accuracy that an unbiased estimator can reach. If $\hat{\theta}$ is an unbiased estimate of θ , the MSE measurements is lower bounded by the CRB such as,

$$\mathbb{E}\|\theta - \hat{\theta}\|^2 \geq \text{Tr}\{\text{CRB}(\theta)\}, \quad (46)$$

where $\text{CRB}(\theta)$ is given as the inverse of the Fisher Information Matrix (FIM), denoted by $\mathbf{F}(\theta)$, such as $\text{CRB}(\theta) = \mathbf{F}(\theta)^{-1}$. An extension for complex-valued parameters can be as in [35], making by structured parameters vector $\theta_c = [\bar{\theta}^T \tilde{\theta}^T]^T$,

where $\bar{\theta} = \text{Re}(\theta)$, and $\tilde{\theta} = \text{Im}(\theta)$. Thereby, with a nuisance parameter γ the expected CRB for complex-valued random parameters is given as

$$\mathbb{E}\|\theta_c - \hat{\theta}_c\|^2 \geq \mathbb{E}_{\bar{\theta}, \tilde{\theta}, \gamma} \left\{ \text{Tr}\{\text{CRB}(\bar{\theta})\} + \text{Tr}\{\text{CRB}(\tilde{\theta})\} \right\}. \quad (47)$$

For an observation vector that follows a complex circular Gaussian distribution, $\mathbf{y} \sim \text{CN}(\boldsymbol{\mu}, \mathbf{R})$, a useful formula, used to obtain the FIM, is the Slepian-Bangs (SB) Formula [51]:

$$\begin{aligned} [\mathbf{F}(\theta)]_{i,j} &= 2\text{Re} \left\{ \left(\frac{\partial \boldsymbol{\mu}}{\partial [\theta_c]_i} \right)^H \mathbf{R}^{-1} \left(\frac{\partial \boldsymbol{\mu}}{\partial [\theta_c]_j} \right) \right\} \quad (48) \\ &+ \text{Tr} \left\{ \left(\frac{\partial \mathbf{R}}{\partial [\theta_c]_i} \right) \mathbf{R}^{-1} \left(\frac{\partial \mathbf{R}}{\partial [\theta_c]_j} \right) \mathbf{R}^{-1} \right\} \quad (49) \end{aligned}$$

such that,

$$\mathbf{F}(\theta_c) = 2 \begin{bmatrix} \bar{\mathbf{M}} & -\tilde{\mathbf{M}} \\ \tilde{\mathbf{M}} & \bar{\mathbf{M}} \end{bmatrix}, \quad (50)$$

and by deriving analytically $\mathbf{F}(\theta_c)^{-1}$ using the schur complement method and considering the trace operator we obtain

$$\text{Tr}\{\text{CRB}(\bar{\theta})\} = \frac{1}{2} \text{Tr} \left\{ \left(\bar{\mathbf{M}} + \tilde{\mathbf{M}} \bar{\mathbf{M}}^{-1} \tilde{\mathbf{M}} \right)^{-1} \right\}, \quad (51)$$

$$\begin{aligned} \text{Tr}\{\text{CRB}(\tilde{\theta})\} &= \frac{1}{2} \text{Tr} \left\{ \bar{\mathbf{M}}^{-1} - \bar{\mathbf{M}}^{-1} \tilde{\mathbf{M}} \left(\bar{\mathbf{M}} + \right. \right. \\ &\quad \left. \left. + \tilde{\mathbf{M}} \bar{\mathbf{M}}^{-1} \tilde{\mathbf{M}} \right)^{-1} \tilde{\mathbf{M}} \bar{\mathbf{M}}^{-1} \right\}. \quad (52) \end{aligned}$$

The matrices $\bar{\mathbf{M}}$ and $\tilde{\mathbf{M}}$ are defined in posterior subsections according to parameters of observation.

The CRB derivations for proposed semi-blind receiver are split into two parts. In the first part, we derive the CRB for the IRS-BS channel \mathbf{H} , whereas in the second part the CRB for the UT-IRS channel \mathbf{G} is derived.

A. CRB for the UT-IRS channel

Here, the UT-IRS channel \mathbf{G} is viewed as unknown nuisance, and the CRB is derived for the IRS-BS channel \mathbf{H} . Let

$$\theta_c = [\mathbf{g}^T \tilde{\mathbf{g}}^T]^T, \quad \mathbf{g} = \text{vec}(\mathbf{G}) \quad (53)$$

$$\gamma = [\mathbf{h}^T \tilde{\mathbf{h}}^T \text{vec}(\mathbf{X})^T]^T, \quad (54)$$

where,

$$\boldsymbol{\mu}_2 = \mathbf{C}\mathbf{g} \quad \text{and} \quad \mathbf{R}_2 = \sigma^2 \mathbf{I}_{TKM}. \quad (55)$$

The CRB for \mathbf{G} is given by summing (51) and (52) where $\bar{\mathbf{M}} = \text{Re}\{\mathbf{C}^H \mathbf{R}^{-1} \mathbf{C}\}$ and $\tilde{\mathbf{M}} = \text{Im}\{\mathbf{C}^H \mathbf{R}^{-1} \mathbf{C}\}$, where $\mathbf{C}^H \mathbf{R}^{-1} \mathbf{C}$ can be expanded as follows

$$\begin{aligned} \mathbf{C}^H \mathbf{R}^{-1} \mathbf{C} &= (1/\sigma^2) (\boldsymbol{\Psi}^T \diamond (\mathbf{X} \otimes \mathbf{H}))^H (\boldsymbol{\Psi}^T \diamond (\mathbf{X} \otimes \mathbf{H})) \\ &= (1/\sigma^2) (\boldsymbol{\Psi}^* \boldsymbol{\Psi}^T \odot (\mathbf{X} \otimes \mathbf{H})^H (\mathbf{X} \otimes \mathbf{H})) \\ &= (1/\sigma^2) (\boldsymbol{\Psi}^* \boldsymbol{\Psi}^T \odot (\mathbf{X}^H \mathbf{X} \otimes \mathbf{H}^H \mathbf{H})). \quad (56) \end{aligned}$$

Under the assumption that $\boldsymbol{\Psi}$ is a semi-unitary matrix satisfying $\boldsymbol{\Psi}^* \boldsymbol{\Psi}^T = K \mathbf{I}_{LN}$ (see our discussion in Appendix B), we have

$$\mathbf{C}^H \mathbf{R}^{-1} \mathbf{C} = (K/\sigma^2) (\mathbf{I}_{LN} \odot (\mathbf{X}^H \mathbf{X} \otimes \mathbf{H}^H \mathbf{H})). \quad (57)$$

Note that according to (57), $\mathbf{C}^H \mathbf{R}^{-1} \mathbf{C}$ is a real-valued diagonal matrix, which implies $\widetilde{\mathbf{M}} = \mathbf{0}$. As a consequence (50) is block diagonal matrix, meaning that the real and imaginary parts are decoupled. Plugging (57) into (51) and (52), the CRB for \mathbf{G} is obtained.

B. CRB for the IRS-BS channel

Here, the IRS-BS channel \mathbf{H} is treated as an unknown nuisance and the CRB is derived for the UT-IRS channel \mathbf{G} . Thus

$$\boldsymbol{\theta}_c = [\widetilde{\mathbf{h}}^T \widetilde{\mathbf{h}}^T]^T, \quad \mathbf{h} = \text{vec}(\mathbf{H}) \quad (58)$$

$$\boldsymbol{\gamma} = [\widetilde{\mathbf{g}}^T \widetilde{\mathbf{g}}^T \text{vec}(\mathbf{X})^T]^T. \quad (59)$$

Applying the $\text{vec}(\cdot)$ operator to (15), we obtain the following noisy observation vector

$$\mathbf{y}_1 = (\mathbf{F} \otimes \mathbf{I}_M) \mathbf{h} = \mathbf{P} \mathbf{h}, \quad (60)$$

where, $\mathbf{y}_1 = \text{vec}(\mathbf{Y}_1)$ and $\mathbf{y}_1 \sim CN(\boldsymbol{\mu}_3, \mathbf{R}_3)$, and

$$\boldsymbol{\mu}_3 = \mathbf{P} \mathbf{h} \quad (61)$$

$$\mathbf{R}_3 = \sigma^2 \mathbf{I}. \quad (62)$$

We have $\overline{\mathbf{M}} = \text{Re}\{\mathbf{P}^H \mathbf{R}_2^{-1} \mathbf{P}\}$ and $\widetilde{\mathbf{M}} = \text{Im}\{\mathbf{P}^H \mathbf{R}_2^{-1} \mathbf{P}\}$. Then,

$$\begin{aligned} \mathbf{P}^H \mathbf{R}_2^{-1} \mathbf{P} &= (1/\sigma^2) (\mathbf{F} \otimes \mathbf{I}_M)^H (\mathbf{F} \otimes \mathbf{I}_M) \\ &= (1/\sigma^2) (\mathbf{F}^H \mathbf{F} \otimes \mathbf{I}_M)^H. \end{aligned} \quad (63)$$

Finally, from the Slepian-Bangs formula, the CRB for \mathbf{H} is obtained by summing (51) and (52).

APPENDIX B

DESIGN OF \mathbf{W} AND \mathbf{S} AND ITS IMPLICATIONS

In this appendix, we discussed the design of the coding matrix \mathbf{W} and the IRS phase shift matrix \mathbf{S} from their Khatri-Rao product combination $\boldsymbol{\Psi} = \mathbf{W} \diamond \mathbf{S} \in \mathbb{C}^{LN \times K}$. Assuming that $\boldsymbol{\Psi}$ is a Vandermonde matrix constructed by truncating a $K \times K$ DFT matrix to its first LN rows, with $LN \leq K$, \mathbf{W} and \mathbf{S} given by (68) and (69) can be obtained from an exact Khatri-Rao factorization of $\boldsymbol{\Psi}$. Let us consider that $\boldsymbol{\Psi} \in \mathbb{C}^{LN \times K}$, with $LN \leq K$, is a Vandermonde matrix constructed by truncating a $K \times K$ matrix to its first LN rows. Defining $\psi_k \doteq e^{-j2\pi(k-1)/K}$, $k = 1, \dots, K$, as the generators of $\boldsymbol{\Psi}$ yields

$$\boldsymbol{\Psi} = \begin{bmatrix} 1 & 1 & \dots & 1 \\ \psi_1 & \psi_2 & \dots & \psi_K \\ \vdots & \vdots & \dots & \vdots \\ \psi_1^{(LN-1)} & \psi_2^{(LN-1)} & \dots & \psi_K^{(LN-1)} \end{bmatrix}. \quad (64)$$

Since the k -th column of $\boldsymbol{\Psi}$ is a Vandermonde vector, it can be factorized as Kronecker product of two Vandermonde vectors with generators ψ_k^N and ψ_k^k , respectively, as follows

$$\begin{bmatrix} 1 \\ \vdots \\ \psi_k^{(LN-1)} \end{bmatrix} = \begin{bmatrix} 1 \\ \vdots \\ \psi_k^{N(L-1)} \end{bmatrix} \otimes \begin{bmatrix} 1 \\ \vdots \\ \psi_k^{(N-1)} \end{bmatrix}. \quad (65)$$

Defining $\mathbf{W}_{k\bullet} \doteq [1, \psi_k^N, \dots, \psi_k^{N(L-1)}] \in \mathbb{C}^{1 \times L}$ and $\mathbf{S}_{k\bullet} \doteq [1, \psi_k, \dots, \psi_k^{(N-1)}] \in \mathbb{C}^{1 \times N}$, we have

$$\boldsymbol{\Psi}_{\bullet k} = \mathbf{W}_{k\bullet}^T \otimes \mathbf{S}_{k\bullet}^T, \quad k = 1, \dots, K, \quad (66)$$

or, equivalently,

$$\begin{aligned} \boldsymbol{\Psi} &= [\boldsymbol{\Psi}_{\bullet 1}, \dots, \boldsymbol{\Psi}_{\bullet K}] \\ &= [\mathbf{W}_{1\bullet}^T \otimes \mathbf{S}_{1\bullet}^T, \dots, \mathbf{W}_{K\bullet}^T \otimes \mathbf{S}_{K\bullet}^T] \\ &= \mathbf{W}^T \diamond \mathbf{S}^T \in \mathbb{C}^{LN \times K}, \end{aligned} \quad (67)$$

where

$$\mathbf{W} = \begin{bmatrix} \mathbf{W}_{1\bullet} \\ \vdots \\ \mathbf{W}_{K\bullet} \end{bmatrix} = \begin{bmatrix} 1 & \psi_1^N & \dots & \psi_1^{N(L-1)} \\ \vdots & \vdots & \ddots & \vdots \\ 1 & \psi_K^N & \dots & \psi_K^{N(L-1)} \end{bmatrix} \in \mathbb{C}^{K \times L}, \quad (68)$$

and

$$\mathbf{S} = \begin{bmatrix} \mathbf{S}_{1\bullet} \\ \vdots \\ \mathbf{S}_{K\bullet} \end{bmatrix} = \begin{bmatrix} 1 & \psi_1 & \dots & \psi_1^{(N-1)} \\ \vdots & \vdots & \ddots & \vdots \\ 1 & \psi_K & \dots & \psi_K^{(N-1)} \end{bmatrix} \in \mathbb{C}^{K \times N}. \quad (69)$$

In order to show that the assumption $\boldsymbol{\Psi}^* \boldsymbol{\Psi}^T = K \mathbf{I}_{LN}$ implies the equivalence between (25) and (26), recall the LS estimation step for \mathbf{G} given by (25), which involves computing the left pseudo-inverse of matrix $\mathbf{C} = [\boldsymbol{\Psi}^T \diamond (\mathbf{X} \otimes \mathbf{H})]$. Taking the Khatri-Rao structure of \mathbf{C} into account, and using property (1), we have

$$\begin{aligned} \mathbf{C}^\dagger &= (\mathbf{C}^H \mathbf{C})^{-1} \mathbf{C}^H \\ &= (\boldsymbol{\Psi}^* \boldsymbol{\Psi}^T \odot (\mathbf{X}^H \mathbf{X} \otimes \mathbf{H}^H \mathbf{H}))^{-1} (\boldsymbol{\Psi} \diamond (\mathbf{X} \otimes \mathbf{H}))^H \\ &= (K \mathbf{I}_{LN} \odot (\mathbf{X}^H \mathbf{X} \otimes \mathbf{H}^H \mathbf{H}))^{-1} (\boldsymbol{\Psi} \diamond (\mathbf{X} \otimes \mathbf{H}))^H. \end{aligned} \quad (70)$$

Defining $\mathbf{Q} = \mathbf{X} \otimes \mathbf{H} \in \mathbb{C}^{TM \times LN}$, and using the property $(\mathbf{A} \otimes \mathbf{B})(\mathbf{C} \otimes \mathbf{D}) = (\mathbf{A} \mathbf{C} \otimes \mathbf{B} \mathbf{D})$, equation (70) can be rewritten as

$$\mathbf{C}^\dagger = (1/K) (\mathbf{I}_{LN} \odot (\mathbf{Q}^H \mathbf{Q}))^{-1} (\boldsymbol{\Psi} \diamond \mathbf{Q})^H. \quad (71)$$

Since the Hadamard product in (71) will null out the non-diagonal terms of the Gramian $\mathbf{Q}^H \mathbf{Q}$, this equation can be simplified to

$$\mathbf{C}^\dagger = (1/K) \boldsymbol{\Sigma}_{\mathbf{Q}}^{-1} (\boldsymbol{\Psi} \diamond \mathbf{Q})^H, \quad (72)$$

where $\boldsymbol{\Sigma}_{\mathbf{Q}}$ is given in (27).
