Parallel square-root statistical linear regression for inference in nonlinear state space models

Fatemeh Yaghoobi, Adrien Corenflos, Sakira Hassan, Simo Särkkä

Abstract—In this article, we introduce parallel-in-time methods for state and parameter estimation in general nonlinear non-Gaussian state-space models using the statistical linear regression and the iterated statistical posterior linearization paradigms. We also reformulate the proposed methods in a square-root form, resulting in improved numerical stability while preserving the parallelization capabilities. We then leverage the fixed-point structure of our methods to perform likelihood-based parameter estimation in logarithmic time with respect to the number of observations. Finally, we demonstrate the practical performance of the methodology with numerical experiments run on a graphics processing unit (GPU).

Index Terms—parallel state estimation, parallel parameter estimation, square-root method, nonlinear state-space model

I. INTRODUCTION

INFERENCE in linear and nonlinear state-space models (SSMs) is an active research topic with applications in many fields including target tracking, control engineering, and biomedicine [1], [2]. In this article, we are primarily interested in state and parameter estimation problems in state-space models of the form

\begin{align}
  x_k | x_{k-1} &\sim p(x_k | x_{k-1}), \quad k \geq 1, \\
y_k | x_k &\sim p(y_k | x_k), \quad k \geq 1, \\
x_0 &\sim p(x_0),
\end{align}

where \( x_k \in \mathbb{R}^{n_x} \) and \( y_k \in \mathbb{R}^{n_y} \) denote the state and measurement at time step \( k \), \( p(x_k | x_{k-1}) \) is the transition density of the Markov process formed by the states, \( p(y_k | x_k) \) is the conditional density of the measurements, and \( p(x_0) \) is the prior distribution of the state at the initial time step \( k = 0 \).

Specifically, we are interested in solving the smoothing estimation problem, which formally consists in estimating the posterior distribution of state \( x_k \) at time step \( k \) given a set of observations \( y_{1:n} = \{y_1, \ldots, y_n\} \), that is, \( p(x_k | y_{1:n}) \), for \( 1 \leq k \leq n \). Furthermore, when the transition, measurement, and prior densities of the state-space model depend on a vector of unknown parameters \( \theta \in \mathbb{R}^{n_\theta} \), we wish to estimate the latter based on a set of observations.

A solution to the smoothing problem is to compute the marginal posterior distribution of the states recursively by using the so-called sequential Bayesian filtering and smoothing equations (see, e.g., [3]). In the case, when all the distributions defining the SSM are Gaussian, the classical Kalman filtering [3] and Rauch–Tung–Striebel smoothing [4] algorithms provide closed-form analytical solutions to the smoothing problem. When the SSM considered is non-Gaussian, closed-form solutions are usually not available. However, Gaussian approximated solutions can then be obtained by using, for example, Taylor expansions or sigma-point methods, with the extended [1], [5], [6] and the unscented [7]–[10] Kalman filters and smoothers being the most famous respective instances of these two methods.

To improve upon the accuracy of extended and unscented methods for smoothing problems, iterated smoothing methods can be used. Iterated extended Kalman smoothers (IEKS) [11] compute the maximum a posteriori estimate of the state trajectory through analytical linearization of the state-space model. The classical IEKS method can be seen as an instance of the Gauss–Newton method [11] and its convergence can be improved by using line search or Levenberg–Marquardt type of extensions [12]. Iterated sigma-point methods using so-called posterior linearization methodology have been proposed for nonlinear SSMs with additive Gaussian noise [13], as well as the general form [11] [14].

To improve the numerical stability and robustness of filters and smoothers, square-root Kalman filtering and smoothing methods have been introduced [15]–[18]. In these methods, the computations involving covariance matrices are reformulated in terms of their Cholesky factors or similar matrix square roots. This ensures that the covariance matrices are guaranteed to stay positive semidefinite and the number of bits required for a given numerical accuracy is roughly half compared to the conventional covariance matrix formulation. Classically, square-root methods have mainly been needed in short word-length architectures arising in systems with strict energy constraints, but nowadays shorter word lengths are also used in high-performance computing devices to gain more computational speed [19], and hence square-root methods are needed more widely.

However, a disadvantage of the aforementioned filtering and smoothing methods is that they do not allow for parallelization due to their inherent sequential nature. Namely, they are based on sequential applications of the Bayesian filtering and smoothing equations which have to be performed in a certain order and, therefore, cannot be parallelized. This prevents leveraging many of the substantial recent improvements made in parallel computing hardware architectures such as graphics processing units (GPUs) and tensor processing units (TPUs) [19].

A way of solving this problem was recently proposed in [20]–[22], where the solution is to reformulated the Bayesian
filtering and smoothing equations in terms of associative operators allowing for parallel-in-time processing using the associative scan algorithm [23]. These articles already provide parallel solution methods for linear-Gaussian, non-linear with additive Gaussian noise, and finite state-space models. In this article, we extend this class of methods significantly by leveraging the generalized statistical linear regression and iterated posterior linearization methodologies which we combine with this parallel formulation and for which we further derive a square-root form.

The contributions of this article are the following. (i) We extend the iterated parallel filtering and smoothing methods for the additive-noise state-space models [21] to generalized statistical linear regression (GSLR) [14], which makes them applicable to general state-space models of the form (1). (ii) We develop novel parallel-in-time square-root versions of the linear parallel filtering and smoothing methods proposed in [20] and extend them to cover the methods in [21] along with the aforementioned extended methods. (iii) We derive a compute and memory efficient way to perform parallel-in-time parameter estimation in state-space models. (iv) The performance of the proposed methods are then empirically validated on a series of realistic examples run on a GPU.

This paper is organized as follows. In Section II, we provide a short review of parallel Bayesian smoothers, the general linearization method for state-space models, and the square-root filtering and smoothing methods. In Section III, we introduce a parallel-in-time iterated filter and smoother based on GSLR linearization for general state-space models. Sections IV and V are then concerned with developing a square-root extension of the parallel Kalman filter and RTS smoother. In Section VI we derive a square-root version of GSLR for extended and sigma-point linearisations. In Section VII, we show how the fixed-point structure of the proposed methods can be leveraged to efficiently compute the log-likelihood, and gradient thereof, of the state-space model at hand. Finally, in Section VIII we experimentally validate the computational and statistical behavior of the proposed methods for performing state and parameter inference on two different nonlinear models.

II. BACKGROUND

In this section, we briefly present the building blocks of our proposed method. First, we review the general parallel framework introduced in [20]. We then introduce the general-ized statistical linear regression method [14] for state-space models. Finally, we discuss general square-root formulations.

A. Parallel-in-time Bayesian filtering and smoothing

The parallel-scan algorithm [23] is a general algorithm that can be applied to a given set of elements \( \{a_k\}_{k=1}^{n} \), and a binary associative operators \( \otimes \). The algorithm allows to parallelize the computation of the full prefix-sum \( (a_1 \otimes a_2 \otimes \cdots \otimes a_K)_{1 \leq K \leq n} \) to reduce its sequential time complexity from \( O(n) \) to a \( O(\log n) \) parallel span-complexity. This property was used in [20] to provide a parallel formulation of the Bayesian filtering and smoothing operations as follows.

Given two positive functions \( g_1(y) \) and \( g_2(y) \), and two conditional densities \( f_1(x \mid y) \) and \( f_2(x \mid y) \), we define the binary operator \( (f_1, g_1) \otimes (f_2, g_2) := (f_1 \cdot g_1, g_2) \) as

\[
\begin{align*}
    f_{ij}(x \mid z) &= \frac{\int g_j(y) f_j(x \mid y) f_i(y \mid z) dy}{\int g_j(y) f_j(y \mid z) dy}, \\
    g_{ij}(z) &= g_i(z) \int g_j(y) f_i(y \mid z) dy.
\end{align*}
\]

Under this parameterization, [20, Theorem 3] states that \( \otimes \) is associative and that, by selecting \( a_k = (f_k, g_k) \) as

\[
\begin{align*}
    f_k(x_k \mid x_{k-1}) &= p(x_k \mid y_k, x_{k-1}), \\
    g_k(x_{k-1}) &= p(y_k \mid x_{k-1}),
\end{align*}
\]

where \( p(x_1 \mid y_1, x_0) = p(x_1 \mid y_1) \) and \( p(y_1 \mid x_0) = p(y_1) \), then the results of the \( k \)-th prefix sum of the elements \( a_k \) under \( \otimes \) recovers the filtering distribution at step \( k \) as well as the marginal likelihood of the observations, that is,

\[
    a_1 \otimes \cdots \otimes a_k = \left( \begin{array}{c} p(x_k \mid y_{1:k}) \\ p(y_{1:k}) \end{array} \right).
\]

Because \( \otimes \) is associative, we can use the parallel-scan algorithm [23] to parallelize this computation, reducing the complexity from \( O(n) \) to \( O(\log n) \) on parallel hardware.

The smoothing step can be handled similarly as the filtering one. Given two conditional densities \( f_i(x \mid y) \) and \( f_j(y \mid x) \), the binary operator defined as

\[
f_i \otimes f_j := \int f_i(x \mid y) f_j(y \mid z) dy
\]

is associative [20, Theorem 6]. Moreover, by selecting \( a_k \) as

\[
a_k = p(x_k \mid y_{1:k}, x_{k+1}),
\]

with \( a_n = p(x_n \mid y_{1:n}) \), the Bayesian smoothing solution can be calculated as

\[
p(x_k \mid y_{1:n}) = a_k \otimes a_{k+1} \otimes \cdots \otimes a_n
\]

and parallelized using the associative scan [23].

While the general formulation of the associative Bayesian filtering operator would, in theory, allow to leverage associative scan primitives to compute the filtering marginals in logarithmic time, the involved densities do not generally have finite-dimensional parametrizations and hence the operations are intractable. However, for linear Gaussian SSMs, we can [20, Lemma 7] parameterize the element \( a_k \) as a set \( \{A_k, b_k, C_k, \eta_k, J_k\} \) such that:

\[
\begin{align*}
    f_k(x_k \mid x_{k-1}) &= p(x_k \mid y_k, x_{k-1}) \\
    &= N(x_k; A_k x_{k-1} + b_k, C_k), \\
    g_k(x_{k+1}) &= p(y_k \mid x_{k+1}) \propto N_f(x_{k+1}; \eta_k, J_k),
\end{align*}
\]

where \( N \) denotes a Gaussian distribution, and \( N_f \) the information form of a Gaussian distribution.

Consider now the following linear Gaussian (or in fact affine) SSM:

\[
\begin{align*}
x_0 &\sim N(m_0, P_0) \\
x_k &= F_k x_{k-1} + c_k - 1 + q_k - 1, \\
y_k &= H_k x_k + d_k + v_k.
\end{align*}
\]
where \( k = 1, 2, \ldots, n \), \( q_k \sim N(0, \Lambda_k) \), and \( v_k \sim N(0, \Omega_k) \).

The explicit expressions for the elements of \( a_k \) for \( k = 1 \) are then given by [20]

\[
\begin{align*}
    m_1^T &= F_0 m_0 + c_0, \\
    P_1^T &= F_0 P_0 F_0^T + \Lambda_0, \\
    S_1 &= H_1 P_1^T H_1^T + \Omega_1, \\
    K_1 &= P_1^T H_1^T S_1^{-1}, \\
    A_1 &= 0, \\
    b_1 &= m_1^T - K_1 [y_1 - H_1 m_1^T - d_1], \\
    C_1 &= P_1^T - K_1 S_1 K_1^T,
\end{align*}
\]

and, for \( k > 1 \),

\[
\begin{align*}
    A_k &= (I_{n_k} - K_k H_k) F_{k-1}, \\
    b_k &= c_{k-1} + K_k (y_k - H_k c_{k-1} - d_{k-1}), \\
    C_k &= (I_{n_k} - K_k H_k) \Lambda_{k-1}, \\
    K_k &= \Lambda_{k-1} H_k^T S_k^{-1}, \\
    S_k &= H_k A_{k-1} H_k^T + \Omega_k,
\end{align*}
\]

so that, for all \( k \geq 1 \),

\[
\begin{align*}
    J_k &= (H_k F_{k-1})^T S_k^{-1} H_k F_{k-1}, \\
    \eta_k &= (H_k F_{k-1})^T S_k^{-1} H_k (y_k - H_k c_{k-1} - d_k).
\end{align*}
\]

The resulting parametric version of the associative filtering operator [2] is then given by \( \{A_{ij}, b_{ij}, C_{ij}, \eta_{ij}, J_{ij}\} \equiv \{A_{ij}, b_{ij}, C_{ij}, \eta_{ij}, J_{ij}\} \), where [20] Lemma 8]

\[
\begin{align*}
    A_{ij} &= A_j (I_{n_i} + C_i J_j) - A_i, \\
    b_{ij} &= A_j (I_{n_i} + C_i J_j) - (b_i + C_i \eta_j) + b_j, \\
    C_{ij} &= A_j (I_{n_i} + C_i J_j) - C_i A_j^T + C_j, \\
    \eta_{ij} &= A_i^T (I_{n_i} + J_i C_i) - (\eta_i - J_i b_j) + \eta_i, \\
    J_{ij} &= A_i^T (I_{n_i} + J_i C_i) - J_i A_i + J_i,
\end{align*}
\]

so that the associative scan algorithm recovers the parameters of the Kalman filter solution via [4]. The Kalman filter means and covariances can then be extracted from the associative scan results as \( b_k \) and \( C_k \). The resulting parallel Kalman filtering algorithm is summarized in Algorithm 1.

**Algorithm 1** Parallel Kalman filter

**Input:** Measurements \( y_{1:n} \), initial mean and covariance \( (m_0, P_0) \), SSM with parameters given in [2].

**Output:** Parallel filtering means \( m_{0:n}^f \) and covariances \( P_{0:n}^f \).

1. for \( k \leftarrow 0 \) to \( n \) do (Compute in parallel)
2. Compute \( A_k, b_k, C_k, \eta_k, J_k \) using (10) or (11).
3. Compute \( \eta_k, J_k \) using (12).
4. Set \( a_k = \{A_k, b_k, C_k, \eta_k, J_k\} \).
5. end for
6. Set \( \{A_k, b_k, C_k, \eta_k, J_k\}^n_{k=0} = \text{AssociativeScan}\left(\otimes, \{a_k\}^n_{k=0}\right) \), where \( \otimes \) is defined in (13).
7. Set \( m_{0:n}^f = m_0, P_{0:n}^f = P_0 \), and extract \( m_{1:n}^f = b_{1:n}, P_{1:n}^f = C_{1:n} \).

Similarly as for the filtering case, we can derive tractable equations for the smoothing distribution of a linear Gaussian SSM. In order to do so, we assume that we calculated the filtering results in parallel beforehand as per Algorithm 1. Then based on [20] Lemma 9, we can use the following representation for the element of \( a_k \)

\[
p(x_k \mid y_1:k, x_{k+1}) = N(x_k; E_k x_{k+1} + g_k, L_k)
\]

where the initial parameters \( \{E_k, g_k, L_k\} \), for \( 0 \leq k < n \), are

\[
E_k = P_k F_k^T (F_k P_k F_k^T + \Lambda_k)^{-1}, \\
g_k = m_k^f - E_k (F_k m_k^f + c_k), \\
L_k = P_k^f - E_k F_k P_k^f.
\]

and for \( k = n \),

\[
E_n = 0, \quad g_n = m_n^f, \quad L_n = P_n^f.
\]

The smoothing results can then be computed by applying the parallel associative scan algorithm backwards in time, and the smoothing means and covariances can be picked up as the resulting elements \( g_k \) and \( L_k \). Algorithm 2 summarizes the parallel RTS smoothing method.

**Algorithm 2** Parallel RTS smoother

**Input:** Filtering results \( m_{0:n}^f \) and \( P_{0:n}^f \), SSM with parameters in [2].

**Output:** Parallel smoothing means \( m_{0:n}^s \) and covariances \( P_{0:n}^s \).

1. for \( k \leftarrow 0 \) to \( n \) do (Compute in parallel)
2. Compute \( a_k = \{E_k, g_k, L_k\} \) using (15) or (16).
3. end for
4. Set \( \{E_k, g_k, L_k\}^n_{k=0} \rangle = \text{ReverseAssociativeScan}\left(\otimes, \{a_k\}^n_{k=0}\right) \), where \( \otimes \) is defined by (17).
5. Extract \( m_{0:n}^s = g_{0:n}, P_{0:n}^s = L_{0:n} \).

Using independent linearizations across time steps, the Gaussian method can be extended to nonlinear models with additive Gaussian noises, allowing its use in the context of iterated extended and sigma-point smoothers [21].

**B. Generalized statistical linear regression**

The statistical linear regression (SLR) method was first proposed as a linearization technique for nonlinear filtering problems in [24]. It generalizes all over the unscented method [9] while allowing for the use of other integration methods too. The generalized statistical linear regression (GSLR) [14] in turn generalizes over SLR by allowing to approximate a general nonlinear non-Gaussian system as an affine transformation of a Gaussian random variable.

In the SLR method, we are given a nonlinear function \( y = g(x) \) of a random variable \( x \) such that its first two moments
The GSLR method \cite{14} considers a generalization of the SLR mean squared error to Gaussian with covariance relationship is ubiquitous in state estimation problems, where the measurement is a function of the state and some noise \( e \): \( y = g(x, e) \), but it also covers more general cases. In particular, given the two conditional moments \( E[y | x] \) and \( V[y | x] \) of \( y \), we can find the best affine approximation \( y \approx Hx + d + r \) in terms of mean square error while matching the covariance. The solution is again given by \cite{18}, with the additional complexity that the moments involved in the calculation now need to be computed using tower laws:

\[
E[y] = E[E[y | x]], \quad V[y] = E[V[y | x]] + E[V[y | x]], \quad C[y, x] = C[E[y | x], x].
\]  

Since the integrals involved in computing the quantities in (19) are not tractable in the general case, we have to resort to approximations. Two widely used classes of methods available to do so are the Taylor series expansion and sigma-point methods.

In (first-order) Taylor expansion methods, we linearize \( E[y | x] \) around an arbitrary point \( \hat{x} \) as follows \cite{14}:

\[
E[y | x] \approx E[y | \hat{x}] + (V_x E[y | x])(\hat{x})(x - \hat{x}), \quad V[y | x]_{i,j} \approx V[y | \hat{x}]_{i,j}.
\]  

Provided that the first and second moments of \( x \) are known, we can therefore compute approximations for all the quantities in (19), and therefore (18).

On the other hand, sigma-point methods consider a weighted approximation of the density of \( x \sim \sum_q w^{(n)} q \delta(x - \chi^n) \), where \( \delta \) is the Dirac distribution. The quantities in (19) can then be approximated as empirical averages, for example \cite{14}:

\[
E[y] \approx \sum_n w^{(n)} E[y | x = \chi^n].
\]  

In the case when the random variable \( x \) is Gaussian, a wide range of sigma-point methods is available \cite{2} for this purpose.

C. General triangular square-root method

In filtering and smoothing problems, we need to propagate the covariance matrix of the state on the prediction and update steps. While these operations theoretically preserve the symmetry and positiveness of the matrices, in practice, we operate on finite word-length computers which causes errors during arithmetic operations \cite{16}. As a result, the numerical arrays representing the covariance matrices might not remain positive definite, in particular, when the state-space model at hand is ill-conditioned, or when the number of measurements is large. A solution to this problem is given by square-root methods \cite{13}, \cite{16} which propagate a square-root of the covariance matrix instead of the plain covariance matrix in the filtering and smoothing equations.

In this article, we use square-root methods based on triangular (Cholesky) square-roots of covariance matrices. Similarly to \cite{17}, in order to propagate the square-root form of the covariance matrices through the filtering and smoothing equations, we leverage the QR-decomposition algorithm, and we define the triangulation operator as \( \text{Tria}(A) \) for matrix \( A \in \mathbb{R}^{n \times m} \) as \cite{17}:

- Compute the QR-factorization of \( A^T \), that is, determine the orthogonal matrix \( Q \in \mathbb{R}^{m \times n} \) and the upper triangular matrix \( R \in \mathbb{R}^{n \times n} \) with non-negative diagonal entries such that \( A^T = QR \).
- Define the triangulation of \( A \) as \( \text{Tria}(A) = R^T \).

The triangulation operator has the following properties:

1) For any matrix \( A \in \mathbb{R}^{n \times m} \), \( \text{Tria}(A) \) is a lower triangular matrix of size \( n \times n \).
2) For any matrix \( A \in \mathbb{R}^{n \times m} \), we have \( \text{Tria}(A)^T \text{Tria}(A)^T = AA^T \).

In particular, the second property above implies that, for any block matrix \( C = (A \ B) \in \mathbb{R}^{n \times (m+k)} \), with \( A \in \mathbb{R}^{n \times m} \) and \( B \in \mathbb{R}^{n \times k} \), we have

\[
\text{Tria}(C)^T \text{Tria}(C)^T = AA^T + BB^T,
\]  

allowing to sum covariance matrices in their square-root form.

Another numerically sensitive operation arising in Kalman filtering and smoothing equations consists in the subtraction of two positive definite matrices. Unfortunately, the triangulation method cannot be used to directly compute the square-root of expressions of the needed form \( AA^T - BB^T \). However, provided that \( AA^T - BB^T \) is positive definite, we can compute its square-root by iteratively applying rank-1 downdate \cite{25} to \( A \), iterating over the columns of \( B \). We denote this operation by \( \text{DownDate}(A,B) \).

III. Parallel filter and smoother based on GSLR posterior linearization

This section presents parallel iterated filters and smoothers based on GSLR linearization. It generalizes the parallel iterated filtering and smoothing methodology of \cite{21} to generalized statistical linear regression (GSLR). As shown in \cite{13}, \cite{14}, a single iteration of the GSLR-based posterior linearization filtering and smoothing consists of two steps:

1) Use the smoothing result from the previous iteration to linearize the dynamic and measurement models of the nonlinear system at all time steps via GSLR.
2) Run Kalman filter and smoother on the linearized system.

In order to parallelize the above steps, we need to parallelize the linearization as well as the Kalman filter and smoother. Below, we provide details on how to find the linearized parameters for a general SSM \cite{1}. Having obtained the linearized parameters, we can successively apply the Algorithms \cite{1} and \cite{2} to obtain the parallel iterated method.
A. Parallel generalized statistical linear regression

We now describe the procedure for finding the linearized representation

\[ x_k \approx F_{k-1} x_{k-1} + c_{k-1} + q_{k-1}, \quad (23a) \]
\[ y_k \approx H_k x_k + d_k + v_k, \quad (23b) \]

of the SSM \( \mathbf{H} \) at hand. Here, \( q_k \) and \( v_k \) are transition and observation Gaussian noises with covariance matrices \( \Lambda_k \) and \( \Omega_k \), respectively. In order to perform the procedure iteratively, we consider a sequence of such representations:

\[ x_k \approx F_{k-1}^{(i)} x_{k-1} + c_{k-1}^{(i)} + q_{k-1}, \quad (24a) \]
\[ y_k \approx H_k^{(i)} x_k + d_k^{(i)} + v_k, \quad (24b) \]

and define the parameters appearing at iteration \( i \) as:

\[ \Gamma_{1:n}^{(i)} = \{ F_{0:n-1}^{(i)}, c_{0:n-1}^{(i)}, \Lambda_{0:n-1}^{(i)}, H_{1:n}^{(i)}, d_{1:n}^{(i)}, \Omega_{1:n}^{(i)} \}, \quad (25) \]

where \( \Lambda_{0:n-1}^{(i)} \) and \( \Omega_{1:n}^{(i)} \) are the covariance matrices of the centered Gaussian random variables \( d_{k}^{(i)} \) and \( v_{k}^{(i)} \), respectively.

Given the set of linearized parameters \( \Gamma_{1:n}^{(i)} \), we can then compute the parameters at iteration \( i + 1 \) by applying the GSLR method to the transition and observation densities \( p(x_k \mid x_{k-1}) \) and \( p(y_k \mid x_k) \), respectively, over the current linearized estimate of the smoothing distribution marginals \( p(x_k \mid y_{1:n}, \Gamma_{1:n}^{(i)}) \). For all \( k \geq 1 \), we compute the following quantities in parallel:

\[ F_{k-1}^{(i+1)} = \mathbb{C}[E[x_k \mid x_{k-1}], x_{k-1}] \mathbb{V}[x_{k-1}]^{-1}, \quad (26a) \]
\[ c_{k-1}^{(i+1)} = E[E[x_k \mid x_{k-1}] - F_{k-1}^{(i)} E[x_{k-1}]], \quad (26b) \]
\[ \Lambda_{k-1}^{(i+1)} = \mathbb{V}[x_k \mid x_{k-1}] + \mathbb{V}[E[x_k \mid x_{k-1}]] - F_{k-1}^{(i)} \mathbb{V}[x_{k-1}] F_{k-1}^{(i) \top}, \quad (26c) \]

where the expectations are taken over \( p(x_{k-1} \mid y_{1:n}, \Gamma_{1:n}^{(i)}) \), and

\[ H_k^{(i+1)} = \mathbb{C}[E[y_k \mid x_k], x_k] \mathbb{V}[x_k]^{-1}, \quad (27a) \]
\[ d_k^{(i+1)} = E[E[y_k \mid x_k] - H_k^{(i)} E[x_k]], \quad (27b) \]
\[ \Omega_k^{(i+1)} = \mathbb{V}[y_k \mid x_k] + \mathbb{V}[E[y_k \mid x_k]] - H_k^{(i)} \mathbb{V}[x_k] H_k^{(i) \top}, \quad (27c) \]

where the expectations are taken over \( p(x_k \mid y_{1:n}, \Gamma_{1:n}^{(i)}) \). Importantly, the approximate smoothing marginals are Gaussian, and are therefore fully represented by their corresponding means \( m_{0:n}^{(i)} \) and covariances \( P_{0:n}^{(i)} \). While the conditional expectations and covariances involved in (26) and (27) are not necessarily tractable, we can then approximate them by using a Taylor expansion or sigma-point based integration as in (20) and (21), respectively. Crucially, this results in a method that is fully independent across all steps \( k \), so that it can be fully parallelized across all steps.

Algorithm 3 Parallel iterated filter and smoother based on GSLR linearization

**Input:** Initial smoothing means and covariances estimates \( \{ m_{0:n}^{(0)}, P_{0:n}^{(0)} \} \), number of iterations \( M \).

**Output:** Parallel smoothing means and covariances \( \{ m_{0:n}^{(M)}, P_{0:n}^{(M)} \} \) at the last iteration.

1: for \( i \leftarrow 1 \) to \( M \) do
2: \{ Compute linearization parameters \( \Gamma_{1:n}^{(i)} \} \)
3: for \( k \leftarrow 1 \) to \( n \) do \{ Compute in parallel \}
4: Compute \( F_{k-1}^{(i)} c_{k-1}^{(i)} \) and \( \Lambda_{k-1}^{(i)} \) using (26) and \( \{ m_{k-1}^{(i-1)}, P_{k-1}^{(i-1)} \} \).
5: Compute \( H_k^{(i)} d_k^{(i)} \) and \( \Omega_k^{(i)} \) using (27) and \( \{ m_{k}^{(i-1)}, P_{k}^{(i-1)} \} \).
6: end for
7: Run Algorithm [1] on the linearized model to compute \( \{ m_{0:n}^{(i)}, P_{0:n}^{(i)} \} \).
8: Run Algorithm [2] on the linearized model to compute \( \{ m_{0:n}^{(i)}, P_{0:n}^{(i)} \} \).
9: end for

B. Parallel Kalman filtering and smoothing on the linearized model

After obtaining the linearization above, we then need to run Kalman filter and smoother on the linearized model. This can be done in parallel by using Algorithms [1] and [2]. The end-to-end procedure is summarized in Algorithm [5] which is the generalized version of the method developed in [21] nonlinear SSMs with additive Gaussian noise.

IV. PARALLEL SQUARE-ROOT FILTER FOR LINEAR SYSTEMS

In order to derive a square-root version of the GSLR-based iterated smoothing method presented in Section III, we first need to derive a square-root form for the linear Gaussian method developed in [20]. That method can then be used to solve the Kalman filtering and smoothing subproblems arising in the parallel GSLR method described in Section III. In this section, we focus on deriving the square-root form of the parallel Kalman filter in Algorithm [1] and we come back to the corresponding RTS smoother in the next section.

A. Initialization parameters

The first aim is to find the square-root version of the initialization parameters in Equations (10), (11), and (12). To do so, we aim to rewrite the parameters \( C_k, S_k \) in (11), and \( J_k \) in (12) as \( C_k = U_k U_k^\top, S_k = Y_k Y_k^\top \), and \( J_k = Z_k Z_k^\top \), respectively. Given these factorizations, we can then define the associative elements for parallel square-root filtering as the sets:

\[ \Pi_k^f = \{ A_k, b_k, U_k, \eta_k, Z_k \}. \quad (28) \]

We now consider the SSM with parameters in (29), except that \( \Lambda_k = S\Lambda_k S^\top \) and \( \Omega_k = S\Omega_k S^\top \) are given in their Cholesky form. Also, we assume that we have the mean and the square-root of covariance, \( m_0, N_0 \), of the initial posterior distribution. Then in order to find the square-root form of (10), by (22),
we compute the square-root version of the prediction step of Kalman filter as:

\[ m^\dagger = F_0m_0 + c_0, \]
\[ N^\dagger_1 = \text{Tria}(F_0N_0^\T S_{\lambda_0}), \]

where \( N^\dagger_1 [N^\dagger_1]^\T = P^\dagger_1 \). For the update step of Kalman filter, we can use

\[
\begin{pmatrix}
H_1N^\dagger_1 & S_{\Theta_1} \\
N^\dagger_1 & 0
\end{pmatrix}
\begin{pmatrix}
H_1N^\dagger_1 & S_{\Theta_1} \\
N^\dagger_1 & 0
\end{pmatrix}^\T
= \begin{pmatrix}
H_1P^\dagger_1H_1^\T + \Omega & H_1P^\dagger_1 \\
H_1P^\dagger_1 & P^\dagger_1H_1^\T
\end{pmatrix}.
\]

(30)

We define the following matrix using Tria:

\[
\begin{pmatrix}
\Psi_{11} & 0 \\
\Psi_{21} & \Psi_{22}
\end{pmatrix} = \text{Tria}\left(\begin{pmatrix}
H_1N^\dagger_1 & S_{\Theta_1} \\
N^\dagger_1 & 0
\end{pmatrix}\right).
\]

(31)

Then, by applying (22) in (31), we obtain:

\[
Y_1 = \Psi_{11},
K_1 = \Psi_{21}(\Psi_{11})^{-1},
A_1 = 0,
b_1 = m^\dagger_1 + K_1[y_1 - H_1m^\dagger_1 - d_1],
U_1 = \Psi_{22}.
\]

(32)

For the other steps, the initialization parameters \( A_k \) and \( b_k \) in (11) will remain the same in the square-root version. For the parameters \( (Y_k, K_k, U_k) \) we can use

\[
\begin{pmatrix}
H_kS_{\lambda_{k-1}} & S_{\Theta_k} \\
S_{\lambda_{k-1}} & 0
\end{pmatrix}
\begin{pmatrix}
H_kS_{\lambda_{k-1}} & S_{\Theta_k} \\
S_{\lambda_{k-1}} & 0
\end{pmatrix}^\T
= \begin{pmatrix}
H_kA_k & H_k^\T A_k \\ A_k^\T & A_k^\T
\end{pmatrix}
\]

(33)

and we can apply the following triangularization rule:

\[
\begin{pmatrix}
\Psi_{11} & 0 \\
\Psi_{21} & \Psi_{22}
\end{pmatrix} = \text{Tria}\left(\begin{pmatrix}
H_kS_{\lambda_{k-1}} & S_{\Theta_k} \\
S_{\lambda_{k-1}} & 0
\end{pmatrix}\right).
\]

(34)

By using (22), (33), and (34) we thus get:

\[
Y_k = \Psi_{11},
K_k = \Psi_{21}(\Psi_{11})^{-1},
U_k = \Psi_{22}.
\]

(35)

For the information filter parameters in (12) we have:

\[
\eta_k = Z_kY_k^{-1}(y_k - H_kc_{k-1} - d_k),
Z_k = F_k^\T H_k^\T Y_k^\T.
\]

(36)

However, when formulated this way, \( Z_k \) is not a square matrix when \( n_x \neq n_y \). In order to make the matrix \( Z_k \) square, we can either extend it with zero columns to the right when \( n_x > n_y \)

\[
Z_k = \begin{pmatrix}
F_k^\T & H_k^\T
\end{pmatrix} \begin{pmatrix}
Y_k^{-1} & 0
\end{pmatrix}
\]

(37)

or replace it with \( \text{Tria}(Z_k) \) when \( n_x < n_y \).
which gives the following factorization:

\[ A_j(I_{n_x} + C_i J_j)^{-1} C_i A_j^\top = [A_j U_i Z_{11}^\top] [A_j U_i Z_{11}^\top]^\top. \quad (48) \]

Equation (48) can be summed with \( C_j \) by using the triangularization property (22) to give

\[ C_{i j} = A_j(I_{n_x} + C_i J_j)^{-1} C_i A_j^\top + C_j. \]

For \( i i \), we further need:

\[
(I_{n_x} + J_j C_i)^{-1} J_j = (I_{n_x} - \Xi_{21} \Xi_{11}^\top U_i) J_j = U_i \Xi_{21} \Xi_{11}^\top \Xi_{21}^\top = \Xi_{21} \Xi_{21}^\top - \Xi_{21} \Xi_{21}^\top \Xi_{21}^\top = \Xi_{22} \Xi_{22}^\top.
\]

(49)

Using (49) will give us \( A_i^\top(I_{n_x} + J_j C_i)^{-1} J_j A_i = [A_i \Xi_{22}] [A_i \Xi_{22}]^\top \), which can be summed with \( J_i \) using the triangularization property (22) again to give \( J_{i j} \).

Having all the necessary steps, the computation of the parameters in \( \Pi_{f j} \) from \( \{A_{i j}, b_{i j}, U_{i j}, \eta_{i j}, Z_{i j}\} \) and \( \Pi_{f j} \) from \( \{A_{i j}, b_{i j}, U_{i j}, \eta_{i j}, Z_{i j}\} \) can be summarized as follows:

\[
A_{i j} = A_j A_i - A_j U_i \Xi_{11}^\top \Xi_{21} A_i,
\]

\[
b_{i j} = A_j(I_{n_x} - U_i \Xi_{11}^\top \Xi_{21}) \left( b_i + U_i \Xi_{11}^\top \eta_i \right) + b_j,
\]

\[
U_{i j} = \text{Tria} \left( (A_j U_i \Xi_{11}^\top U_i)^\top \right),
\]

\[
\eta_{i j} = A_i^\top (I_{n_x} - U_i \Xi_{11}^\top U_i) \left( \eta_i - Z_i^\top b_i \right) + \eta_i,
\]

\[
Z_{i j} = \text{Tria} \left( (A_i \Xi_{22} Z_i) \right),
\]

where \( \Xi_{11}, \Xi_{21}, \) and \( \Xi_{22} \) are defined by (40).

We summarize the square root version of the parallel filtering step in Algorithm 4.

---

**Algorithm 4** Square-root version of parallel Kalman filter

**Input:** Measurements \( y_{1:n} \), initial mean and square-root covariance \((m_0, N_0)\), SSM with parameters given in (9) with \( \Lambda_k = S \Lambda_k S^\top \Lambda_k \) and \( \Omega_k = S \Omega_k S^\top \Omega_k \).

**Output:** Filtering means \( m_{0:n} \) and square roots of covariances \( N_{0:n} \).

---

**V. Parallel square-root smoother for linear systems**

The aim in this section is to find the square-root version of the parallel RTS smoother of Algorithm 2. Similarly to the filtering step, we need to develop square-root formulations of both the initialization and combination steps.

**A. Initialization parameters**

In order to derive the square root of the smoothing initialization elements in (15), we first define them as:

\[ \Pi_k = \{ E_k, g_k, D_k \}, \]

where \( L_k = D_k D_k^\top \). We consider the SSM with parameters in (9) with \( \Lambda_k = S \Lambda_k S^\top \Lambda_k \) and \( \Omega_k = S \Omega_k S^\top \Omega_k \). Also, we assume that we have obtained the result of the filtering distribution as \( m_k^{f} \) and \( N_k^{f} \) such that \( P_k^{f} = N_k^{f} [N_k^{f}]^\top \).

Similarly as in Section IV, we can factor

\[
\left( F_k N_k^f \quad S_{\Lambda_k} \right)^\top \left( F_k N_k^f \quad S_{\Lambda_k} \right) = \left( F_k N_k^f \quad S_{\Lambda_k} \right)^\top \left( F_k P_k^{f} \quad P_k^{f} \right),
\]

and define

\[
\Phi_{11} = \text{Tria}( (F_k N_k^f \quad S_{\Lambda_k})^\top)
\]

By considering \( L_k = D_k D_k^\top \) and applying (22) in (52) and (53) the square-root versions of the parameters (15) can be computed as:

\[
E_k = \Phi_{21} \Phi_{11}^{-1},
\]

\[
g_k = m_k^{f} - E_k (F_k m_k^{f} + c_k),
\]

\[
D_k = \Phi_{22}.
\]

**B. Combination**

To define the square-root version of the smoothing combination (17), it suffices to derive the combination rule for the covariances square roots. Let us consider two elements \( a_i = \{ E_i, g_i, L_i \} \) and \( a_j = \{ E_j, g_j, L_j \} \). Their combination via (17) produces \( L_{i j} = E_i L_j E_i^\top + L_i \), which, for \( L_i = D_i D_i^\top \) and \( L_j = D_j D_j^\top \), can readily be expressed as

\[
D_{i j} = \text{Tria}( (E_i D_j \quad D_i) ).
\]

Algorithm 5 presents the procedure of computing the initialization and combination of the parallel square-root smoother.

---

**VI. PARALLEL SQUARE-ROOT ITERATED POSTERIOR LINEARIZATION**

We now turn to developing a square-root version of the parallel GLSR filtering and smoothing methods in Section III. To do this, we first derive square-root versions of the linearization parameters (26) and (27) for first order Taylor series expansion and sigma-point linearizations. Given the linearized SSMs, we will then be able to compute the filter and smoother results by applying the algorithms presented in Sections IV and V.
Assume that the Cholesky decompositions of the conditional covariances of transition and observation densities, \( \mathbb{V}[x_k \mid x_{k-1}] \) and \( \mathbb{V}[y_k \mid x_k] \), defined as \( S_x[x_k \mid x_{k-1}] \) and \( S_y[y_k \mid x_k] \), respectively, are tractable. The first goal is to calculate the square-root version of the linearized parameters \( \Gamma \) in (25). We define the square-root linearization parameters, \( \Gamma^{\text{sqrt}} \), in each iteration, \( i \), as:

\[
\Gamma^{\text{sqrt}(i)}_{1:k} = \{ F_{k-1}^{(i)}, c_{k-1}^{(i)}, S_{\Lambda_k}^{(i)}, H_{1:k}^{(i)}, d_{1:k}^{(i)}, S_{\Omega_k}^{(i)} \}, \tag{56}
\]

where \( S_{\Lambda_k} \) and \( S_{\Omega_k} \) are the square-root matrices of \( \Lambda_k \) and \( \Omega_k \), respectively. In the following, we derive the parameters of \( \Gamma^{\text{sqrt}} \), using Taylor series expansion and sigma-point methods.

### Algorithm 5 Square-root version of parallel RTS smoother

**Input:** Filtering results \( m_{0:n}^f \) and \( N_{0:n}^f \), SSM given in (9), and \( A_k = S_{\Lambda_k} S_{\Lambda_k}^T \) and \( \Omega_k = S_{\Omega_k} S_{\Omega_k}^T \),

**Output:** Smoothing means \( m_{0:n}^s \) and square-root of covariances \( N_{0:n}^s \).

1. Initialize \( \Pi_k^* = \{ E_k, g_k, D_k \} \}
2. for \( k \leftarrow 0 \) to \( n \) do \{Compute in parallel\}
3. \( k = n \) then
4. \( (E_n, g_n, D_n) \leftarrow (0, m_{n}^f, N_{n}^f) \)
5. else
6. Compute \( E_k, g_k, \) and \( D_k \) using (54).
7. end if
8. end for
9. Set \( (\Pi_k^*)_{k=0}^n = \text{ReverseAssociativeScan}(\otimes, (\Pi_k^*)_{k=0}^n) \), where \( \otimes \) is defined by the first two equations in (17) along with (55).
10. Extract \( m_{0:n}^s = y_{0:n}, N_{0:n}^s = D_{0:n} \).

### A. Square-root iterated Taylor series expansion

Iterated Taylor series expansion relies on linearizing around the previous smoothing mean \( m_{k}^s \) which is the best available result [13]. Now, using (24), the conditional mean and square-root of the covariance in (26) can be approximated as follows:

\[
E[x_k \mid x_{k-1}] \approx E[x_k \mid x_{k-1}](m_{k-1}^s) + \nabla_x E[x_k \mid x_{k-1}](m_{k-1}^s)(x_{k-1} - m_{k-1}^s),
\]

\[
S_x[x_k \mid x_{k-1}] \approx S_x[x_k \mid x_{k-1}](m_{k-1}^s).
\tag{57}
\]

Then, by applying (57) in (26), the square-root version of the first order Taylor series expansion method will be as follows:

\[
F_{k-1} = \nabla_x E[x_k \mid x_{k-1}](m_{k-1}^s),
\tag{58a}
\]

\[
c_{k-1} = E[x_k \mid x_{k-1}](m_{k-1}^s) - F_{k-1} E[x_{k-1}],
\tag{58b}
\]

\[
S_{\Lambda_{k-1}} = S_x[x_k \mid x_{k-1}](m_{k-1}^s). \tag{58c}
\]

The same procedure can be applied to find the parameters \( (H_k, d_k, \Omega_k) \). The conditional mean and square-root covariance needed for (27) are:

\[
E[y_k \mid x_k] \approx E[y_k \mid x_k](m_k^s)
\]

\[
+ \nabla_y E[y_k \mid x_k](m_k^s)(x_k - m_k^s),
\tag{59}
\]

\[
S_x[y_k \mid x_k] \approx S_x[y_k \mid x_k](m_k^s).
\]

Now by substituting (59) in (27), the square-root linearized parameters are:

\[
H_k = \nabla_x E[y_k \mid x_k](m_k^s),
\]

\[
d_k = E[y_k \mid x_k](m_k^s) - H_k E[x_k],
\tag{60}
\]

\[
S_{\Omega_k} = S_y[y_k \mid x_k](m_k^s).
\]

### B. Square-root iterated sigma-point linearization method

The idea of the iterated sigma-point linearization method is to approximate the expectation of a nonlinear function using a set of \( s \) sigma points \( \chi_1, \ldots, \chi_s \) and their associated mean weights \( w_1^\mu, \ldots, w_s^\mu \) and covariance weights \( w_1^\gamma, \ldots, w_s^\gamma \). Here sigma-points are obtained according to posterior means and square-root covariances of the smoothing density \( p(x_k \mid y_{1:n}) \) [18], [28]. There are different choices for sigma-points and weights which lead to different sigma-point methods [29]. Here we assume that the covariance weights are positive \( w_i^\gamma > 0 \).

In this linearization method, we need both the mean and the square root of the covariance of the smoothing density, \( m_k^s \) and \( N_k^s \). Then, in order to compute the parameters \( (F_{k-1}, c_{k-1}, S_{\Lambda_k-1}) \), we first obtain the transformed sigma-point as \( Z_{x,i} = E[x_k \mid x_{k-1}](\chi_i) \) and consequently define:

\[
\bar{z}_x = E[E[x_k \mid x_{k-1}]] \approx \sum_{i=1}^s w_i^m Z_{x,i}. \tag{61}
\]

Then, by applying (21) in (26) and using (61) we have:

\[
F_{k-1} = \sum_{i=1}^s w_i^c (Z_{x,i} - \bar{z}_x)(\chi_i - m_{k-1}^s)^\top (N_{k-1}^s[N_{k-1}^s]^-1),
\]

\[
c_{k-1} = \bar{z}_x - F_{k-1} m_{k-1}^s. \tag{62}
\]

In order to find the root of the covariance as per (26a) we define:

\[
Z_x = [\sqrt{w_1^\gamma(Z_{x,1} - \bar{z}_x)} \ldots \sqrt{w_s^\gamma(Z_{x,s} - \bar{z}_x)}]. \tag{63}
\]

Now, by defining \( S_{x,i} = S_x[x_k \mid x_{k-1}](\chi_i) \) for \( i = 1, \ldots, s \) and applying (21) in (26a), the latter equation can be approximated as:

\[
\Lambda_{k-1} \approx \sum_{i=1}^s \left( w_i^c S_{x,i} S_{x,i}^\top + Z_x Z_x^\top - F_{k-1} N_{k-1}^s[N_{k-1}^s]^-1 F_{k-1}^\top \right.
\]

To find the square root of \( \Lambda_k \), first we find the square root of the first two parts on the right-hand side of (64) as follows:

\[
S_{\Lambda_{k-1}} = \text{Tri}(Z_x, \sqrt{w_1^\gamma S_{x,1}}, \ldots, \sqrt{w_s^\gamma S_{x,s}}), \tag{65}
\]

Then, using DownDate function (see Section II-C), the square-root of \( \Lambda_{k-1} \) can be obtained as

\[
S_{\Lambda_{k-1}} \approx \text{DownDate}(S_{\Lambda_{k-1}}', F_{k-1} N_{k-1}^s). \tag{66}
\]

The same procedure can be applied in order to obtain the linearization parameters \( (H_k, d_k, \Omega_k) \) of (27). To do so, we
consider $Z_{y,i} = \mathbb{E}[y_k | x_k](\mathcal{X}_i)$, and $S_{x,i} = \mathcal{S}[y_k | x_k](\mathcal{X}_i)$ for $i = 1, \ldots, s$. Then, by using the mean
\[
\bar{z}_y = \mathbb{E}[\mathbb{E}[y_k | x_k]] \approx \sum_{i=1}^{s} w_i^m Z_{y,i} \tag{67}
\]
and the following definition
\[
Z_y = \left[ \sqrt{w_1^s (Z_{y,1} - \bar{z}_y)} \cdots \sqrt{w_s^s (Z_{y,s} - \bar{z}_y)} \right], \tag{68}
\]
we can compute the linearization parameters:
\[
H_k \approx \sum_{i=1}^{s} w_i^c (Z_{y,i} - \bar{z}_y) (X_i - m_k^s) \mathbb{T} (N_k^s [N_k^s])^{-1},
\]
dk \approx \bar{z}_y - H_k m_k^s,
\]

\[
S_{0,k} = \text{Tri} \left( \left( Z_y, \sqrt{w_1^s S_{y,1}}, \ldots, \sqrt{w_s^s S_{y,s}} \right) \right),
\]

\[
S_{0,k} \approx \text{DownDate} (S_{0,i}, H_k N_k^s).
\]

### C. The final parallel square-root algorithm

We can now combine the aforementioned square-root results in order to find a square-root version of the parallel iterated filter and smoother based on GSLR linearization presented in Section III. To be specific, a single iteration of this method consists in the following two steps:

1. Use the square-root results of the smoother from the previous iteration in GSLR to linearize the dynamic and measurement models of the nonlinear system on all time steps $k = 1, \ldots, n$. The linearization can be performed based on Taylor series expansion (Sec. VI-A) or sigma-point methods (Sec. VI-B).

2. Run the square-root version of Kalman filter and smoother on the linearized system in Algorithms 4 and 5.

Having defined the standard and square-root methods, we can iterate the filtering and smoothing algorithms until convergence. This recovers the optimal nominal trajectory, defined here as $n_0^s := \{m_{0,n}^s, P_{0,n}^s\}$ for the standard method and $n_0^s := \{m_{0,n}^s, N_{0,n}^s\}$ for the square-root method. This is summarized in Algorithm 6.

### VII. PARAMETER ESTIMATION

In order to derive parallel state estimation methods in the previous sections, we have assumed that the state-space model from which the observations $y_{1:n}$ were generated was known exactly. However, in many practical applications, the actual expressions for the state-space observation model $p(y_k | x_k)$, transition model $p(x_k | x_{k-1})$, and prior $p(x_0)$ are not known and, instead, need to be estimated from the observed data.

#### A. Problem formulation

A typical way to proceed is to assume a parametric form for the state-space model (1), namely that its components depend on some parameters:

\[
p(x_k | x_{k-1}, \theta_k), \quad p(y_k | x_k, \phi_k), \quad p(x_0 | \theta_0).
\]

Under these notations, the parameter estimation task consists in estimating $\theta := [\theta_0, \theta_1, \phi_1, \theta_2, \phi_2, \ldots, \theta_n, \phi_n] \in \mathbb{R}^{nu}$, either in the form of a point estimate $\theta^*$, or as a posterior distribution $p(\theta | y_{1:n})$. To estimate these, many classical methods – such as maximum likelihood [30], maximum a posteriori [31], or gradient-based Markov chain Monte Carlo estimation methods [32] e.g., Hamiltonian Monte Carlo] – require being able to compute the log-likelihood of the system $\log p(y_{1:n} | \theta)$ as well as, in some cases, its gradient with respect to $\theta$, also called the score function. In this section, we show how these two quantities can be efficiently computed in parallel.

For the sake of conciseness, in the remainder of this section, we will only consider the covariance formulation of our proposed method as given in Algorithm 3. However, the analysis remains unchanged if one considers instead the square-root formulation developed in Sections VI and VII.

#### B. Parallel computation of the (pseudo) log-likelihood

For general state-space models, the log-likelihood $\log p(y_{1:n}) = p(y_{1:n} | \theta)$ can be computed iteratively using the identity

\[
\log p(y_{1:n}) = \sum_{k=1}^{n} \log \int_{x_k} p(y_k | x_k) p(x_k | y_{1:k-1}) dx_k, \tag{71}
\]

where we drop the dependency on $\theta$ for simplicity. In the case of linear Gaussian state-space models (LGSSMs), the integrals appearing in (71) are available in closed form, and we can compute them using the observation predictive means and covariances. As was suggested in [20], for LGSSMs, this formulation allows to compute the log-likelihood $\log p(y_{1:n})$ in parallel by first computing the filtering distribution at each time step $p(x_k | y_{1:n}) \sim \mathcal{N}(m_k^p, P_k^p)$, then all the terms in (71) $\ell_k = \log \mathcal{N}(y_k | m_k^p, P_k^p)$, where $m_k^p$ and $P_k^p$ are the predictive mean and covariance of $y$, and summing them for all $k$’s. The span complexity of computing the filtering distribution in

---

**Algorithm 6** Parallel square-root iterated filter and smoother based on Taylor and sigma-point linearization

**Input:** Initial smoothing means and square-root covariances estimates for the whole trajectory at iteration $i = 0$ as $\{m_{0:n}^{s(0)}, N_{0:n}^{s(0)}\}$, number of iterations $M$.

**Output:** Smoothing means and covariances at the final iteration $\{m_{0:n}^{s(M)}, N_{0:n}^{s(M)}\}$.

1: for $i \leftarrow 1$ to $M$ do
2: \{Compute linearization parameters\}
3: for $k \leftarrow 1$ to $n$ do \{Compute in parallel\}
4: Compute $\Gamma_k^{ap} = \{F_k^{1,1}, c_k^{1,1}, S_k^{1,1}, H_k, d_k, S_k\}$ by using a Taylor series expansion (Sec. VI-A) or sigma-point methods (Sec. VI-B).

7: Run Algorithm 4 on the linearized model to compute $\{m_{0:n}^{f(i)}, N_{0:n}^{f(i)}\}$.
8: Run Algorithm 5 on the linearized model to compute $\{m_{0:n}^{s(i)}, N_{0:n}^{s(i)}\}$.
9: end for
at each time step is \( O(\log(n)) \), the span complexity of computing all the terms \( \ell_k \) given the filtering distribution is \( O(1) \), and the span complexity of summing all these terms is \( O(\log(n)) \) too, so that the total span complexity of computing the log-likelihood in LGSSMs is \( O(\log(n)) \).

In the context of general state-space models, however, we cannot usually obtain analytical expressions for the integrals appearing in (71). Instead, these can be approximated by leveraging the same linearization rules that were used to compute the filtering estimates. Specifically, all the terms in (71) can be approximated from the linearized system (23), producing a pseudo-log-likelihood \( \hat{\ell}(\theta) \) which is an estimate of the “true” log-likelihood \( \log p(y_{1:n} \mid \theta) \) of the system. As discussed in Section III the linearized parameters of the system (23) are computed based on either iterated Taylor or sigma-points approximations in span complexity \( O(\log(n)) \), resulting in a total span complexity of \( O(\log(n)) \) for computing the pseudo log-likelihood, for both our proposed square-root and standard formulations.

C. Constant-memory parallel computation of the score function

Because the pseudo log-likelihood \( \hat{\ell}(\theta) \) of the non-linear SSM (1) is the “true” log-likelihood \( \log p(y_{1:n} \mid \Gamma_{1:n}) \) of the linearized model (23), one could simply apply the reverse accumulation chain rule, for example, by using automatic differentiation libraries, in order to compute the gradient of \( \hat{\ell} \). This was, for example, done in [33] to learn parameters of temporal Gaussian processes.

While this method would result in an efficient algorithm to compute the score function of LGSSMs, it would suffer from several drawbacks if applied to Gaussian approximated non-linear SSMs directly. Indeed, in this case, the linearized SSM parameters \( \Gamma_k \)’s depend on the final nominal trajectory \( n_{0:n} \) used during the linearization step. In turn, the final nominal trajectory depends on the previously estimated linearized parameters as well as \( \theta \), forming a chain of dependency down to the initial nominal trajectory. Furthermore, in order to proceed with reverse accumulation, all the intermediary results involved in computing the pseudo log-likelihood need to be stored. Because the total number of iterations \( M \) required for the nominal trajectory to converge is not necessarily known in advance, the memory cost of naively “unrolling” the convergence loop would be unknown at compilation time. However, thanks to the fixed-point structure of Algorithm 6 we can derive a constant-memory algorithm to compute the gradient of quantities depending on the filtering and smoothing distributions (which include the pseudo log-likelihood in particular).

For notational simplicity, let us only consider the case when \( n_x = n_y = \dim(\theta) = 1 \), the general case follows from taking element-wise derivatives instead. When using the mean-covariance approach of Section III, computing the gradient of the covariance-based nominal trajectory w.r.t. the state-space model parameters \( \theta \) at convergence.

**Algorithm 7** Fixed-point algorithm for computing the gradient of the covariance-based nominal trajectory w.r.t. the state-space model parameters \( \theta \) at convergence.

**Input:** Optimal trajectory \( n_{0:n} = \{m_{0:n}^\theta, P_{0:n}^\theta\} \) computed with Algorithm 6 for parameter \( \theta \).

**Output:** \( \{d_P^\theta, d_m^\theta\} \) computed at the optimal nominal trajectory \( n_{0:n} \) and \( \theta \).

1. Initialize \( \frac{dm_k^\theta}{d\theta}, \frac{dP_k^\theta}{d\theta} \) for all \( k = 0, \ldots, n \)
2. Compute \( \frac{dKS_m^\theta}{d\theta}, \frac{dKS_p^\theta}{d\theta}, \frac{dKS_{m_k}^\theta}{d\theta}, \frac{dKS_{p_k}^\theta}{d\theta} \) at the optimal nominal trajectory \( n_{0:n} \) and \( \theta \)
3. Iterate (73) until convergence.

\( \hat{\ell} \) consists in applying the chain rule to \( \log p: \)

\[
\frac{d\hat{\ell}}{d\theta} = \sum_{k=0}^{n} \left[ \frac{d\hat{\ell}}{dF_{k-1}} \left( \frac{\partial F_{k-1}}{\partial \theta} \right) + \frac{\partial F_{k-1}}{\partial \theta} \left( \frac{\partial m_{k-1}^s}{\partial \theta} + \frac{\partial P_{k-1}^s}{\partial \theta} \right) \right] .
\]

(72)

To compute the full derivative, we need to compute the following quantities

1) \( \frac{\partial F_{k-1}}{\partial \theta}, \frac{\partial F_{k-1}}{\partial \theta}, \frac{\partial F_{k-1}}{\partial \theta} \): this is easily done by differentiating through the Taylor or sigma-points linearization algorithms.

2) \( \frac{dP_k^\theta}{d\theta}, \frac{dP_{k}^\theta}{d\theta} \): naively, this would require to apply the chain rule through all the steps of the convergence loop in Algorithm 6.

Thankfully, \( n_{0:n} \) verifies the fixed point identity \( n_{0:n}^* = KS(n_{0:n}, y_{1:n}, \theta) \), where KS is the Kalman smoother operator given by Algorithm 5. Therefore, we can leverage the implicit function theorem as in [34] to show that

\[
\frac{dm_{0:n}^\theta}{d\theta} = \frac{dKS_{m_k}^\theta}{d\theta} \frac{dm_k^\theta}{d\theta} + \frac{dKS_m^\theta}{d\theta},
\]

\[
\frac{dP_{0:n}^\theta}{d\theta} = \frac{dKS_{p_k}^\theta}{d\theta} \frac{dP_k^\theta}{d\theta} + \frac{dKS_p^\theta}{d\theta},
\]

(73)

where \( KS_{m_k}^\theta \) and \( KS_{p_k}^\theta \) are the mean and covariance outputs of the smoother operator KS at time \( k \), respectively. This ensures that, for any \( k = 0, \ldots, n \), \( \frac{dm_k^\theta}{d\theta} \) and \( \frac{dP_k^\theta}{d\theta} \) verify a linear fixed-point equation, which, provided that the operator norm of all \( \frac{dKS_{m_k}^\theta}{d\theta}, \frac{dKS_{p_k}^\theta}{d\theta} \) is less than 1, admits a unique solution which can be computed by iterating it. We can therefore replace the memory-unbounded reverse accumulation calculation of the gradient of the optimal nominal trajectory by a memory-constant iterative procedure. The full procedure is summarized in Algorithm 7.

**Remark 1:** It is worth noting that (73) and the related routine in Algorithm 7 *a priori* seem to have a \( O(T^2) \) memory cost due to the apparent need of computing all the different combinations of derivatives. However, automatic differentiation libraries typically require manipulating vector-Jacobian (or Jacobian-vector) products rather than full Jacobians [35], so that the actual implementation of Algorithm 7 only incurs a memory cost of \( O(T) \), in line with that of computing the log-likelihood in the first place.
When \( n^* \) has been computed, all the operations happening within the loop of Algorithm [7] are fully parallelizable, apart from computing the terms \( \frac{\partial \text{KS}^{(n^*)}_{m,n}}{\partial m_{q,n}} \) and \( \frac{\partial \text{KS}^{(n^*)}_{m,n}}{\partial q_{m,n}} \), and the final sum of the incremental log-likelihood terms, which all have span complexity \( O(\log(n)) \) as they share the same computational graph as the one used to compute the smoothing solution itself. The total span complexity of computing the (pseudo) score function is therefore \( O(\log(n)) \).

VIII. EXPERIMENTAL RESULTS

In this section, we empirically demonstrate the performance of our proposed framework. For this, we consider a population model [14], [36] and a coordinated turn model [11], [37]. We aim to show the effectiveness of our methods in terms of computational complexity, robustness, and parameter estimation. All the experiments are conducted using the NVIDIA® GeForce RTX 3080 Ti 12 GB with 10240 CUDA cores, and leveraging the Python library JAX [35] for parallelization and automatic differentiation support. The code to reproduce the results can be found at https://github.com/EEA-sensors/sqrt-parallel-smoothers/.

A. Parallel inference in a general SSM

We now evaluate the performance of the general parallel method for a fully nonlinear non-Gaussian SSM. This generalizes the experiment done in [21] which was only concerned with additive noise models. We consider a particular nonlinear population model, the stochastic Ricker model, described in [36], and also used in [14]. It takes the form

\[
\begin{align*}
x_k &= \log(a) + x_{k-1} - \exp(x_k) + q_k, \\
y_k \mid x_k &\sim \text{Poisson}(b \exp(x_k)), \\
x_0 &\sim \delta(x_0 - \log(c)), \\
q_k &\sim N(0, Q_k).
\end{align*}
\]  

(74)

Here, \( a, b, c \) are hyperparameters and \( x_k \) is a one-dimensional state, and the measurement \( y_k \) is conditionally distributed according to a Poisson distribution with rate \( b \exp(x_k) \). For this experiment, the hyperparameters are chosen to be \( a = 44.7, b = 10, c = 7, \) and \( Q_k = 0.3^2 \).

Our aim is to compare the performance of the covariance-based sequential and parallel methods in the sense of time span complexity. To this end, we perform \( M = 100 \) iterations of the iterated extended (IEKS) and cubature Kalman smoothing (ICKS) on the model for different number of observations.

The average (over 100 repetitions) run times of sequential and parallel IEKS and ICKS methods are reported in Fig. 1. This figure shows that the parallel methods are generally faster compared to the sequential. However, the differences are less prominent for shorter time horizons (say, \( n = 10 \)), and more significant with long time horizon. The run times of sequential IEKS and ICKS are increasing linearly with respect to the number of the time steps, whereas the parallel IEKS and ICKS exhibit a much better complexity scaling.

B. Computational complexity of parallel square-root methods

In this experiment, the goal is to show the effectiveness of our proposed square-root method in terms of computational complexity in a high dimensional state-space setting. We consider the problem of tracking a maneuvering target with a coordinated turn model [11] given bearing-only sensor measurements. Other uses of this model can be found, for example, in [28] and [37]. The state is a 5-dimensional vector \( x = [p_x, p_y, \dot{p}_x, \dot{p}_y, \omega]^T \) containing the position \((p_x, p_y)\), the speed \((\dot{p}_x, \dot{p}_y)\), and the turn rate \(\omega\) of the target. The bearing is measured by two sensors located at known positions \((s^i_x, s^i_y)\) for \( i = 1, 2 \). We follow the parameterization of [28], and take the noise parameters and time step to be \( q_1 = 0.1, q_2 = 0.1 \), and \( T = 0.01 \).

Similarly as in Section VIII-A, in this experiment, consider observations sets with size varying from 10 to 5,000, report the average run time (computed over 100 runs) of running \( M = 10 \) iterations of the iterated smoothing methods. The average run time for different linearizations is reported in Fig. 2. As expected, the parallel square-root method is faster than its sequential square-root method.

C. Robustness of parallel square-root methods

In this part, we study the same coordinated turn model as described in Section VIII-B above to show how the square-root
method improves the stability of the algorithm, as compared to the covariance-based one, when using 32-bit floating-point numbers. In order to assess the stability of the method, for each chosen number of observations, we simulate 15 independent sets of observations and run square-root and covariance based parallel iterated extended and cubature Kalman smoother for $M = 20$ iterations. We then report the divergence rate for a given method and number of observations, as defined by the percentage of NaN (not a number) resulting log-likelihood estimates. The result is shown in Fig. 3 and shows that square-root methods achieve higher stability in comparison to the covariance-based (standard) method.

D. Parallel parameter estimation

In this section, we again consider the coordinated turn model to demonstrate the performance of the proposed parameter estimation algorithm in the sense of the accuracy of the parameter estimation and of the reduction in computational cost achieved by using the parallel method on GPU. Here, the parameter that we intend to find is the standard deviation of the first sensor, $\sqrt{R_{1,1}}$. The ground-truth standard deviation of the first measurement noise is taken to be 0.05. The parameters used in this study are the same parameters used by [29]. In order to assess the performance of the method, we simulate 10 different trajectories and calibrate the model on varying size subsets of the generated sets of observations.

To compute the log-likelihood of the model, and compute the gradient thereof, we use Taylor series and several sigma-point linearization methods (cubature, unscented, and Gauss–Hermite) and the covariance-based corresponding iterated smoothers. The parameter is then estimated by maximum likelihood estimation, where the optimization is carried out using the L-BFGS-B based algorithm with known (automatically computed) Jacobian. Fig. 4a shows the RMSE (root mean square error), over the 10 simulations, of the resulting estimates to the true parameter. As it can be seen, by increasing the time steps, the estimation is being more accurate, and all linearization methods converge at the same speed with comparable accuracy, with Gauss–Hermite linearization giving the best results.

Another important benefit of the proposed parallel method is its reduced compute time. To show this, we report the GPU run time for sequential and parallel methods for different linearization schemes. Figure 4b shows how the computational complexity of the parallel methods for different linearization is superior to their sequential counterparts.

IX. Conclusion

In this paper, we have presented a novel parallel-in-time inference method for general state-space models. First of
all, we have generalized [21] to non-additive state-space models by leveraging the generalized statistical linear regression of [14]. In order to improve on the numerical stability of the algorithm, we further developed a square-root formulation of the parallel-in-time Kalman filter and RTS smoother of [20]. By reformulating the generalized statistical linear regression equations in terms of square-root of covariance matrices, we then obtained a square-root version of our parallel-in-time nonlinear smoother. Finally, using the fixed-point structure of the iterated method, we showed how to compute the log-likelihood, and gradient thereof, in parallel for use in parameter estimation. Our experimental results, conducted on a GPU, exhibited the advantages of our proposed inference method in the sense of diminishing time complexity and increasing numerical stability.
