

ON THE ROLE OF TIKHONOV REGULARIZATIONS IN STANDARD OPTIMIZATION PROBLEMS

J. ADRIAZOLA

ABSTRACT. Tikhonov regularization is a common technique used when solving poorly behaved optimization problems. Often, and with good reason, this technique is applied by practitioners in an ad hoc fashion. In this note, we systematically illustrate the role of Tikhonov regularizations in two simple, yet instructive examples. In one example, we use regular perturbation theory to predict the impact Tikhonov regularizations have on condition numbers of symmetric, positive semi-definite matrices. We then use a numerical example to confirm our result. In another example, we construct an exactly solvable optimal control problem that exhibits a boundary layer phenomena. Since optimal control problems are rarely exactly solvable, this brings clarity to how vital Tikhonov regularizations are for the class of problems this example represents. We solve the problem numerically using MATLAB's built-in optimization software and compare results with a Galerkin-type/genetic algorithm. We find the second method generally outperforms MATLAB's optimization routines and we provide the MATLAB code used to generate the numerics.

1. INTRODUCTION

Ill-posed and ill-conditioned problems frequently arise in applied and computational mathematics. To overcome this common challenge, one typically introduces a type of regularization that either converts the problem to a well-posed one or better conditions the resulting computational problem. The Tikhonov regularization technique is often chosen as the first strategy toward this goal and has been successfully applied in several contexts ranging from ill-posed optimal control problems [1,2,9,11,13] to the numerical solution of poorly-conditioned integral equations [15,18–21]. In statistics, the method is better known as ridge regression [10].

To illustrate how Tikhonov regularizations apply in a general optimization setting, consider the problem of finding x_* such that

$$(1) \quad J(x_*) = \min_{x \in X} J(x),$$

subject to

$$(2) \quad f(x) = 0,$$

where $J : X \rightarrow \mathbb{R}$ is called an objective functional, $f : X \rightarrow Y$ is a constraint function, and X, Y are general Banach spaces. Although the problem may be solvable, it may either be too computationally intensive to solve or fail to admit solutions which remain feasible to implement in a scientific or technological application. Thus, one often seeks to define a modified problem

$$(3) \quad J_\varepsilon(x) = J(x) + \varepsilon K(x)$$

while still remaining faithful to the originally intended goal.

Of the many possible pitfalls that may be encountered when attempting to solve an ill-posed problem, one important example is where the optimal solution $x_* \in X$ lacks a desired degree

of regularity or smoothness. A Tikhonov regularization enforces smoothness of solutions to this problem by modifying the objective to include a penalization. A typical choice is setting

$$(4) \quad K(x) = \|x\|_{\dot{H}^1(\Omega)}^2$$

in Equation (3), where $\Omega \subset \mathbb{C}^n$, $n \in \mathbb{Z}^+$, and $\varepsilon \in \mathbb{R}^+$. The notation $\dot{H}^1(\Omega)$ indicates a homogeneous Sobolev space with norm given by $\|Dx\|_{L^2(\Omega)}$, where $L^2(\Omega)$ is the standard Lebesgue (Hilbert) space [12] and D indicates differentiation with respect to elements from Ω . Simply put, the introduction of the regularization penalizes solutions that rapidly vary over Ω .

The problem of finding an optimal value of ε is known in statistics as the so-called bias-variance dilemma [14]. Although an optimal choice of the Tikhonov parameter ε is known in certain circumstances [23], the parameter is typically chosen in an ad hoc manner. Through the simple and instructive examples studied here, we reveal suitable regularization parameters in simpler settings which may guide choices in more complex ones. Of course, choosing suitable regularization parameters in more complex, real-world applications remains to be done on a case-by-case basis.

This work is organized as follows. Section 2 shows how the Tikhonov technique better conditions a symmetric, positive semi-definite matrix whose inverse is desired. There, we quantitatively show the type of impact a small Tikhonov regularization can have on an extremely ill-conditioned matrix. In Section 3, we show an example of an optimal control problem admitting a closed-form solution. Since the problem is exactly solvable, this provides a testbed for standard optimization methods of which we compare two; an interior-point method [4] implemented by MATLAB's `fmincon` and a method, due to Calarco, et al. [6, 7], called the Chopped Random Basis (CRAB) method which we also implement in MATLAB. In Appendix A, we provide MATLAB code reflecting our implementation of the methods used to solve the optimal control problem discussed in Section 3.

2. REGULARIZING AN ILL-CONDITIONED MATRIX

The first example we consider is matrix inversion of an ill-conditioned matrix. Let $n \in \mathbb{Z}^+$ and consider the following optimization problem:

$$(5) \quad \min_{x \in \mathbb{R}^n} J = \min_{x \in \mathbb{R}^n} \left\{ \frac{1}{2} x^\top A x - x^\top b + \frac{\varepsilon}{2} x^\top D^\top D x \right\}$$

where A is some real, symmetric, and positive semi-definite $n \times n$ matrix, $b \in \mathbb{R}^n$, D is some, as of yet, unspecified $n \times m$ matrix, $m \in \mathbb{Z}^+$, and ε is a small, real number. The restrictions placed on A are done so its spectrum can be analyzed in detail.

By taking the gradient of the objective J in Equation (5) with respect to the variable x , we see that the optimal vector x^* satisfies

$$(6) \quad (A + \varepsilon D^\top D) x^* = b.$$

Note that in the case $\varepsilon = 0$, the solution to Equation (6) is given by $x^* = A^{-1}b$. If A is singular, then the task of finding x^* is ill-posed, and if A is nearly-singular, computing x^* is challenging and often requires substantial computational resources for large n .

It is well-known that the condition number of a symmetric, positive semi-definite matrix A , with condition number denoted by $c(A)$, is given by the ratio of its largest eigenvalue to its smallest eigenvalue [17]. For this reason, we aim to better understand the effect of the Tikhonov regularizer $\varepsilon D^\top D$ on the spectrum of A for small enough ε since this informs us of the condition number of the regularized matrix $A + \varepsilon D^\top D$.

To this end, further assume the eigenvalues of A are simple, and consider the asymptotic expansions

$$(7a) \quad \lambda(\varepsilon) \sim \sum_{j=0}^{\infty} \lambda_j \varepsilon^j \quad \text{as } \varepsilon \rightarrow 0,$$

$$(7b) \quad \nu(\varepsilon) \sim \sum_{j=0}^{\infty} \nu_j \varepsilon^j \quad \text{as } \varepsilon \rightarrow 0,$$

where ν_0 and λ_0 are defined as the respective eigenvector/eigenvalue pair of the matrix A . To leading order, we have

$$(8) \quad A\nu_0 = \lambda_0\nu_0,$$

which is automatically satisfied by the definition of ν_0 and λ_0 .

To next order, i.e., $\mathcal{O}(\varepsilon)$, we have

$$(9) \quad (A - \lambda_0 I)\nu_1 = (\lambda_1 - D^T D)\nu_0,$$

where I is the $n \times n$ identity matrix. The Fredholm alternative [17] requires the right-hand side to be orthogonal to the left-eigenvector of A so that Equation (9) is solvable. Since A is symmetric, the left eigenvector of A is simply ν_0^T . The solvability condition of Equation (9) is then given by

$$(10) \quad \lambda_1 = \frac{\nu_0^T D^T D \nu_0}{\nu_0^T \nu_0}.$$

Thus, the resulting condition number is

$$(11) \quad c(A + \varepsilon D^T D) = \frac{\lambda^{\max}}{\lambda^{\min}} \sim \frac{\lambda_0^{\max} + \varepsilon \lambda_1^{\max}}{\lambda_0^{\min} + \varepsilon \lambda_1^{\min}} + \mathcal{O}(\varepsilon^2), \quad \text{as } \varepsilon \rightarrow 0,$$

where $\lambda_0^{\min/\max}$ are, respectively, the smallest and largest eigenvalues satisfying Equation (8) while $\lambda_1^{\min/\max}$ are the smallest and largest numbers satisfying Equation (10). Presumably, λ_0^{\min} is nearly zero, so long as λ_1^{\min} is not, the regularization has a high likelihood of being effective.

Indeed, the asymptotic formula (11) gives a criteria for finding effective A -specific Tikhonov matrices, i.e., the Tikhonov matrix D solves the following max-min problem

$$(12) \quad \max_{D \in \mathcal{D}} \min_{\nu_0 \in \mathcal{V}} \left\{ \frac{\nu_0^T D^T D \nu_0}{\nu_0^T \nu_0} \right\},$$

where \mathcal{D} is the space of all $n \times m$ matrices and \mathcal{V} is the set of eigenvectors of the ill-conditioned matrix A . We do not take up a study of Equation (12) here, and instead leave further investigation for future study.

To better illustrate the effect a Tikhonov regularization has on a nearly singular operator, take as an example the symmetric, positive-definite matrix

$$(13) \quad A = \begin{pmatrix} 1 & 1 \\ 1 & 1 + \mu \end{pmatrix}, \quad \mu > 0$$

which has eigenvalues

$$(14) \quad \lambda_0^{\min} = \frac{1}{2} (\mu + 2 - \sqrt{\mu^2 + 4}), \quad \lambda_0^{\max} = \frac{1}{2} (\mu + 2 + \sqrt{\mu^2 + 4}).$$

and corresponding eigenvectors

$$(15) \quad \nu_0^{\min} = \begin{pmatrix} \frac{1}{2} (-\mu - \sqrt{\mu^2 + 4}) \\ 1 \end{pmatrix}, \quad \nu_0^{\max} = \begin{pmatrix} \frac{1}{2} (-\mu + \sqrt{\mu^2 + 4}) \\ 1 \end{pmatrix},$$

Clearly, A is ill-conditioned since $c(A) \rightarrow \infty$ as $\mu \rightarrow 0$ from above. Indeed, for $\mu = 10^{-6}$, the condition number $c(A) = 4 \times 10^6$ to seven digits of precision. However, the asymptotic result (11) predicts that simply choosing D to be the forward difference operator

$$(16) \quad D = \begin{pmatrix} 1 & 0 \\ -1 & 1 \\ 0 & -1 \end{pmatrix},$$

a choice consistent with Equation (4) in this finite-dimensional setting, and a small regularization parameter of $\varepsilon = 0.01$, the regularized condition number $c(A + \varepsilon D^T D) = 203$ to three digits of precision; a noteworthy improvement. In fact, the asymptotic result is well within the same order of magnitude of the true value of the condition number

$$(17) \quad c(A + \varepsilon D^T D) = \frac{2 + 4\varepsilon + \mu + \sqrt{4 - 8\varepsilon + 4\varepsilon^2 + \mu^2}}{2 + 4\varepsilon + \mu - \sqrt{4 - 8\varepsilon + 4\varepsilon^2 + \mu^2}}$$

which is 67 to two digits of precision.

Rounding out the example, we choose an example vector $b = (\frac{1}{2}, \frac{1}{2})^T$ to demonstrate that we can still solve the matrix inversion in a meaningful way. When $\varepsilon = 0$, the exact solution is given by $x_{\text{unreg}} = (\frac{1}{2}, 0)^T$, while, to three digits of precision and when $\varepsilon = 0.01$, the solution $x_{\text{reg}} = (0.248, 0.248)^T$. The regularized solution has a residual, i.e., $J(x_{\text{reg}})$ when $\varepsilon = 0$, of 1.24×10^{-5} . The vast improvement on the condition number of A , while still remaining faithful to the unregularized numerical computation, clearly demonstrates that even a small Tikhonov regularization can greatly mitigate an extremely ill-conditioned numerical computation.

3. REGULARIZING AN EXACTLY SOLVABLE OPTIMAL CONTROL PROBLEM

The second example we consider is an optimal control problem representative of optimization problems that frequently arise in controlling dispersive waves, e.g. [1, 2, 11]. This optimal control problem, by virtue of its exact solution, helps reveal some of the typical numerical difficulties exhibited by this class of problems. Consider the following Lagrange control problem

$$(18) \quad \min_{u \in \mathcal{U}} J = \min_{u \in \mathcal{U}} \int_0^\pi \left(x + \frac{1}{2}u^2 + \frac{\varepsilon}{2} \left(\frac{du}{dt} \right)^2 \right) dt,$$

where the admissible class $\mathcal{U} = \{u \in H^1([0, \pi]) : u(0) = u(\pi) = 0\}$, subject to the forced harmonic oscillator

$$(19a) \quad \frac{dx}{dt} = p, \quad x(0) = 0,$$

$$(19b) \quad \frac{dp}{dt} = u - x, \quad p(0) = 0.$$

The prescription of boundary conditions in defining the class of admissible controls \mathcal{U} will soon play a critical role when considering the unregularized case, i.e., $\varepsilon = 0$. For ease of notation in what follows, we use overhead dots to denote differentiation with respect to time, e.g., $\dot{x} = \frac{dx}{dt}$.

We recast the problem into a form more amenable to standard tools from the calculus of variations. Using Lagrange multipliers, or costates in the language of optimal control theory and denoted here by $\lambda(t)$ and $\mu(t)$, the equivalent unconstrained saddle-point problem is given by

$$(20) \quad \begin{aligned} & \min_{u \in \mathcal{U}} \int_0^\pi \mathcal{L}(x, \dot{x}, p, \dot{p}, \lambda, \mu, u, \dot{u}) dt \\ & = \min_{u \in \mathcal{U}} \int_0^\pi \left(x + \frac{1}{2}u^2 + \frac{\varepsilon}{2}\dot{u}^2 + \lambda(\dot{x} - p) + \mu(\dot{p} + x - u) \right) dt. \end{aligned}$$

The Euler-Lagrange equations (see, for example, [5, 8, 24]) are given by

$$(21a) \quad \frac{\delta \mathcal{L}}{\delta x} = \frac{\partial \mathcal{L}}{\partial x} - \frac{d}{dt} \frac{\partial \mathcal{L}}{\partial \dot{x}} = 1 - \dot{\lambda} + \mu = 0, \quad \left. \frac{\partial \mathcal{L}}{\partial \dot{x}} \right|_{t=\pi} = \lambda(\pi) = 0,$$

$$(21b) \quad \frac{\delta \mathcal{L}}{\delta p} = \frac{\partial \mathcal{L}}{\partial p} - \frac{d}{dt} \frac{\partial \mathcal{L}}{\partial \dot{p}} = \lambda - \dot{\mu} = 0, \quad \left. \frac{\partial \mathcal{L}}{\partial \dot{p}} \right|_{t=\pi} = \mu(\pi) = 0,$$

$$(21c) \quad \frac{\delta \mathcal{L}}{\delta \lambda} = \frac{\partial \mathcal{L}}{\partial \lambda} = \dot{x} - p = 0, \quad x(0) = 0,$$

$$(21d) \quad \frac{\delta \mathcal{L}}{\delta \mu} = \frac{\partial \mathcal{L}}{\partial \mu} = \dot{p} + x - u = 0, \quad p(0) = 0,$$

$$(21e) \quad \frac{\delta \mathcal{L}}{\delta u} = \frac{\partial \mathcal{L}}{\partial u} - \frac{d}{dt} \frac{\partial \mathcal{L}}{\partial \dot{u}} = u - \mu - \varepsilon \ddot{u} = 0, \quad u(0) = u(\pi) = 0.$$

Note that the costates' terminal conditions, present in Equations (21a) and (21b), are a result of an integration by parts against test functions $\varphi \in C^\infty([0, T])$, which do not necessarily vanish at $t = \pi$, in the derivation of the Euler-Lagrange equations.

By direct integration, it's easy to see the following functions

$$(22a) \quad \lambda_* = -\sin(t),$$

$$(22b) \quad \mu_* = -\cos(t) - 1$$

are the optimal costates. This implies, after using the method of variation of parameters, see e.g. [3], to solve Equation (21e), the optimal control is

$$(23) \quad u_* = \frac{\operatorname{csch}\left(\frac{\pi}{\sqrt{\varepsilon}}\right) \left((\varepsilon + 2) \sinh\left(\frac{\pi-t}{\sqrt{\varepsilon}}\right) + \varepsilon \sinh\left(\frac{t}{\sqrt{\varepsilon}}\right) \right) - \cos(t) - \varepsilon - 1}{\varepsilon + 1}.$$

Additionally, we solve for the optimal state x_* in a similar fashion which results in

$$(24) \quad x_* = \frac{\sqrt{\varepsilon} \operatorname{csch}\left(\frac{\pi}{\varepsilon}\right)}{(\varepsilon + 1)^2} \left(\varepsilon^{3/2} \sinh\left(\frac{t}{\sqrt{\varepsilon}}\right) - \varepsilon \sin(t) \right) - \frac{t \sin(t)}{2(\varepsilon + 1)} + \cos(t) - 1 \\ + \frac{\sqrt{\varepsilon}(\varepsilon + 2) \operatorname{csch}\left(\frac{\pi}{\varepsilon}\right)}{(\varepsilon + 1)^2} \left(\sqrt{\varepsilon} \left(\sinh\left(\frac{\pi-t}{\sqrt{\varepsilon}}\right) - \sinh\left(\frac{\pi}{\sqrt{\varepsilon}}\right) \cos(t) \right) + \cosh\left(\frac{\pi}{\sqrt{\varepsilon}}\right) \sin(t) \right),$$

while the optimal objective J^* is found to be

$$(25) \quad J_* = \sqrt{\varepsilon} \tanh\left(\frac{\pi}{2\sqrt{\varepsilon}}\right) \left(\frac{\coth^2\left(\frac{\pi}{2\sqrt{\varepsilon}}\right)}{(\varepsilon + 1)^2} + 1 \right) - \frac{\pi(2\varepsilon + 3)}{4(\varepsilon + 1)}.$$

With these calculations in hand and further considering any time $0 < t \leq T$, we may take these optimal functions' limits as ε approaches zero from above. We find that

$$(26a) \quad \lim_{\varepsilon \rightarrow 0^+} u_* := u_{\text{limit}} = -1 - \cos(t)$$

$$(26b) \quad \lim_{\varepsilon \rightarrow 0^+} x_* := x_{\text{limit}} = -\frac{1}{2}t \sin(t) + \cos(t) - 1$$

$$(26c) \quad \lim_{\varepsilon \rightarrow 0^+} J_* := J_{\text{limit}} = -\frac{3\pi}{4}.$$

Although the unregularized problem exhibits no features of an ill-posed problem, note that the limiting optimal control fails to remain in the admissible class \mathcal{U} since u_{limit} does not vanish at $t = 0$. However, from the explicit calculation, we have that for each $\varepsilon > 0$, there exists a $u \in \mathcal{U}$ which solves the optimal control problem (18). Thus, taking small values of the regularization parameter ε manifests in a type of boundary layer in the vicinity of $t = 0$ for optimal control u_* .

That is, the optimal control develops a steep gradient at $t = 0$ as $\varepsilon \rightarrow 0^+$, and, consequently, $\lim_{\varepsilon \rightarrow 0^+} \|u_* - u_{\text{limit}}\|_{H^1([0,T])} \neq 0$. The effect this has on numerical computations will be discussed shortly.

We numerically solve optimal control problem (18) in two ways. The first, performed pointwise in time, is to use MATLAB's `fmincon` which implements an interior-point method [4]. The second is to use a method due to Calarco, et al. [6, 7], called the **Chopped Random Basis** (CRAB) method. It relies on choosing controls from the span of an appropriately chosen finite set of basis functions so that the optimization is performed over a set of unknown coefficients. The choice of basis is problem-specific but is always chosen so that controls remain in the appropriate admissible space. The choice of representation we make here is the following sine series:

$$(27) \quad u_r(t) = \sum_{j=1}^N \frac{r_j}{j^2} \sin\left(\frac{2j\pi}{T}\right), \quad t \in [0, T],$$

where the coefficients $r_j \in [-1, 1]$ are parameters to be optimized over. Note that we choose the amplitudes in Equation (27) to decay quadratically because the Fourier series of absolutely continuous functions exhibits this type of decay [22]. In this way, the search space of amplitudes is not severely restricted, yet early iterations of the controls generated by the CRAB method are not highly oscillatory.

FIGURE 1. A numerical solution of optimal control problem (18), with $\varepsilon=1$, via the CRAB method and MATLAB's `fmincon`. Left Panel: The controls found via both numerical methods and the exact optimal control given in closed-form by Equation (23). Right Panel: The states found via both numerical methods and the exact state given in closed-form by Equation (24).

The CRAB method is of Galerkin-type. Recall that the intent behind any Galerkin method is to choose the number of basis functions N simultaneously large enough to define an accurate approximation, yet small enough so that the overall procedure remains computationally inexpensive. For this problem, we find that just 12 modes are sufficient. The optimization problem is now a small-scale nonlinear programming (NLP) problem and can be solved using any number of industry-standard techniques. The technique we use to solve the resulting NLP problem is Differential Evolution (DE) [16].

In our numerical study, we focus on investigating the role of the Tikhonov parameter ε . To this end, we set $\varepsilon = 1$ and show the numerical solution of Problem (18) in Figure 1. We solve the

state equations (19) with MATLAB’s ODE45 solver. The numerics shown there demonstrate the adequacy of both methods used to solve Problem (18). The numerical implementation of these methods is provided in the form of MATLAB code in Appendix A.

By setting $\varepsilon = 1$, we find that we have strongly regularized the problem. This is seen in a pointwise comparison between x_* , shown in Figure 1, and x_{limit} , shown in Figure 2, especially for later times t . Yet, by taking $\varepsilon = 0.001$, we find that both optimization methods struggle to resolve the sharp transition of the control in the boundary layer near $t = 0$. We find $\varepsilon = 0.04$ to be a good intermediate value under the tension of under- and over-regularizing the control problem (the bias-variance dilemma). In this case, we see that the CRAB method successfully finds the optimal control u_* , while `fmincon` develops undesirable oscillations in the control near the boundary layer.

FIGURE 2. Examples of when the Tikhonov parameter ε is small. The conventions here are consistent with Figure 1. The top panels correspond to $\varepsilon = 0.001$ while the bottom panels have $\varepsilon = 0.04$. The bottom panels also include the limiting control and state functions given by Equation (26).

4. CONCLUDING REMARKS

In this work, we provide a pair of standard optimization problems where an application of the Tikhonov regularization technique is crucial. Moreover, they provide instructive examples which can be used in basic courses on numerical linear algebra and optimization. We also demonstrate

the utility of the CRAB method, over more standard numerical optimization methods, when trying to solve control problems that exhibit sharp transition regions in the optimal control.
