Abstract—Bayesian Neural Networks (BNNs) provide a tool to estimate the uncertainty of a neural network by considering a distribution over weights and sampling different models for each input. In this paper, we propose a method for uncertainty estimation in neural networks called Variational Neural Network that, instead of considering a distribution over weights, generates parameters for the output distribution of a layer by transforming its inputs with learnable sub-layers. In uncertainty quality estimation experiments, we show that VNNs achieve better uncertainty quality than Monte Carlo Dropout or Bayes By Backpropagation methods.

Index Terms—Bayesian Neural Networks, Bayesian Deep Learning, Uncertainty Estimation

I. INTRODUCTION

The ability to estimate the uncertainty of prediction in neural networks provides advantages in using high-performing models in real-world problems, as it enables higher-level decision-making to consider such information in further actions. To do so, one needs the neural network to accompany its output with a measurement of its corresponding uncertainty for each input it processes. Several approaches have been introduced to this end, with Bayesian Neural Networks (BNNs) [1]–[3] providing an elegant framework for estimating uncertainty of a neural network by introducing a probability distribution over its weights and sampling different models that are meant to describe the input from different points of view. This allows to determine inputs for which the network predictions are different, leading to a measurement of the network uncertainty in its outputs. Such an approach usually comes with an increased computational cost, but may be valuable for tasks where prediction errors result in high losses, such as autonomous driving, or medical image analysis, or critical infrastructure control.

The choice of the prior weights probability distribution function influences the statistical quality of the model and the computational resources needed to use such neural networks, which creates a possibility to explore different approaches to BNNs by using Gaussian [4], Bernoulli [5], Categorical [6] or other distributions. Sampling from the posterior distribution can be difficult, due to the complex nature of it. This leads to methods that avoid direct computation of the posterior, such as Markov Chain Monte Carlo (MCMC) [7], which constructs a Markov chain of samples \( S_t \) that are distributed following the desired posterior, or Variational Inference [8], which scales better than MCMC and aims to estimate a parametrized distribution that should be close to the exact posterior. How close the distributions are is computed using the Kullback-Leibler (KL) divergence [9], but it still requires the exact posterior. This is overcome by computing an Evidence Lower Bound (ELBO) instead and optimizing it with Stochastic Variational Inference (SVI) [10].

We introduce Variational Neural Networks (VNNs) which do not consider a distribution over weights, but define sub-layers to generate parameters for the output distribution of the layer. To keep computational and memory resource usage practical, we consider a Gaussian distribution with learnable mean and variance. We provide a neural network formulation that describes both related BNNs and the proposed VNNs in a unified manner, and show that VNNs, while being in the same group, as Monte Carlo Dropout (MCD) [5] and Bayes By Backprop (BBB) [4] from the Bayesian Model Averaging (BMA) perspective, achieve better uncertainty quality and retain it with the increasing data dimensionality.

II. BAYESIAN NEURAL NETWORKS

BNNs [1]–[3] consider a distribution over their weights \( p(w|a) \) and a distribution over their hyperparameters \( p(a) \). A predictive distribution over an output \( y \) for a data point \( x \) can be obtained by integrating over all possible hyperparameters and model weights, i.e.:

\[
p(y|x) = \int \int p(y|x, w) p(w|a) p(a) \, da \, dw. \tag{1}
\]

Given a dataset \( D = \{X_t, Y_t\} \), where \( X_t \) and \( Y_t \) are the sets of inputs \( \{x\} \) and targets \( \{y\} \), the distribution of weights can be derived from Bayes’ theorem as \( p(w|D, a) = \frac{p(Y_t|X_t, w)p(w|a)}{p(D)} \), and the corresponding predictive distribution has a form

\[
p(y|x, D) = \int \int p(y|x, w) p(w|D, a) p(a) \, da \, dw. \tag{2}
\]

Classical neural networks can be viewed as BNNs with \( p(a) = \delta(a - \hat{a}) \) and \( p(w|D, a) = \delta(w - \hat{w}_a) \) [3], where \( \hat{a} \) are the selected model hyperparameters, \( \hat{w}_a \) are the weights, optimized by training the model, and \( \delta(x) \) is the Dirac delta function which has values 0 everywhere except at \( x = 0 \) where it equals to 1. In this case, the predictive distribution becomes

\[
p(y|x, D) = \int \int p(y|x, w) p(w|D, a) p(a) \, da \, dw,
\]

\[
= \int p(y|x, w) \delta(w - \hat{w}_a) \delta(a - \hat{a}) \, da \, dw, \tag{3}
\]

which is a distribution dictated by a loss of the network.

When training classical neural networks, hyperparameters are considered fixed at point \( \hat{a} \) and weights are optimized either by maximum likelihood estimation (MLE), i.e.:

This work has received funding from the European Union’s Horizon 2020 research and innovation programme (grant agreement No 871449 (OpenDR)). I. Oleksiienko and A. Iosifidis are with the Department of Electrical and Computer Engineering, Aarhus University, Denmark (e-mail: {io.ail} @ece.au.dk). D. T. Tran is with the Department of Computing Sciences, Tampere University, Finland (e-mail: thanh.tran@tuni.fi).
\[
\begin{align*}
    w_{\text{mle}} &= \arg\max_w \left[ \log p(D|w, \hat{a}) \right] \\
    &= \arg\max_w \left[ \sum_i \log p(Y_i|X_i, w, \hat{a}) \right], \\
    w_{\text{map}} &= \arg\max_w \left[ \log p(w|D, \hat{a}) \right] \\
    &= \arg\max_w \left[ \log p(D|w, \hat{a}) + \log p(w) \right],
\end{align*}
\]

where \( \log p(w) \) is a regularization term.

Due to the complexity of neural networks, direct computation of \( w_{\text{mle}} \) or \( w_{\text{map}} \) cannot be achieved, and therefore approximate methods are used to find these values. The most popular process to estimate the weight values is the Backpropagation algorithm [11], where an initial randomly selected weight initialization and training order. Outputs from the trained model weights. Hypermodels [13] use an additional hyperparameters by defining some of them in the beginning, e.g., by selecting that we want to use a Convolutional Neural Network (CNN). This is a reasonable approach, as it is not practical to iterate through all possible types and structures of networks during training. We are using the neural network formulation \( NN(x) := F^\Lambda(x, w) \), where \( NN(x) \) is a neural network applied to an input \( x \), \( w \) are the trained weights, \( F \) is a neural network function that incorporates structure and other hyperparameters inside it, and \( \Lambda \) is a set of layer implementations, which are used by \( F \) to process layer inputs.

In case of CNNs, \( \Lambda = \{\text{Conv2D}(x, w), \text{FC}(x, w)\} \) results in a regular CNN, where Conv2D(x, w) is a 2D convolutional layer function and FC(x, w) is a fully connected layer function. If we select \( \Lambda = \{\text{Conv2D}(x, w_c \sim \mathcal{N}([\mu_c, \Sigma_c]), \text{FC}(x, w_l \sim \mathcal{N}([\mu_l, \Sigma_l]))\} \) with layer weights sampled from a corresponding Gaussian distribution, then the resulting network is a BBB CNN. Such neural network formulation allows to accurately describe all the discussed uncertainty estimation methods, as well as the proposed VNNs.

III. RELATED WORKS

The use of BNNs in real-world applications is limited due to the complex nature of the possible prior and predictive distributions. Therefore, simplified versions are used. Assumptions that are proposed in different methods below aim to reduce memory, inference and training time, but they come with the cost of reducing the statistical quality of the resulting models. This problem is further discussed in Section [VI] of the paper.

MCD [5] considers a neural network with Dropout [12] added to each layer. The Dropout layer effectively turns off random neurons of the layer by multiplying connection weights with a random binary mask, sampled from a Bernoulli distribution. This allows to avoid overfitting specific neurons. After training, Dropout is replaced by an identity function and all neurons are used for inference. Instead of replacing Dropout with identity, MCD uses it during inference leading to a stochastic model. The model uncertainty for an input is computed by performing inference multiple times and computing mean and variance of predictions. BBB [4] samples model parameters from a Gaussian distribution and trains it using regular Backpropagation. By doing so, the family of models with different weights is sampled from the learned distribution, and the uncertainty of the network is computed as the variation in predictions of different samples.

Ensembles of neural networks [6] can also be used for uncertainty estimation. Ensembles are trained in parallel for the same task, but with different random seeds, which results in different weight initialization and training order. Outputs from members of an ensemble will vary, and this can be used to improve performance by taking an average of their predictions, or to estimate uncertainty by computing the variance of their outputs. Such an approach can be viewed as a BNN with a categorical distribution over weights that randomly selects one of the trained model weights. Hypermodels [13] use an additional model \( \theta = g_c(z) \) to generate parameters for a base model \( f_\theta(x) \). Linear Hypermodels set \( g_c(z) = a + Bz \), \( z \sim \mathcal{N}(0, I) \). Using different samples of \( z \), one can sample different model parameters and estimate uncertainty in the same way as for the aforementioned methods.

IV. VARIATIONAL NEURAL NETWORKS

As introduced in Section [II] a neural network is described by its weights \( w \) and hyperparameters \( \alpha \). Hyperparameters include the structure of the network, i.e., the type and number of layers, their size and connections, etc. Usually, we limit the hyperparameters by defining some of them in the beginning, e.g., by selecting that we want to use a Convolutional Neural Network (CNN). This is a reasonable approach, as it is not practical to iterate through all possible types and structures of networks during training. We are using the neural network formulation \( NN(x) := F^\Lambda(x, w) \), where \( NN(x) \) is a neural network applied to an input \( x \), \( w \) are the trained weights, \( F \) is a neural network function that incorporates structure and other hyperparameters inside it, and \( \Lambda \) is a set of layer implementations, which are used by \( F \) to process layer inputs.

In case of CNNs, \( \Lambda = \{\text{Conv2D}(x, w), \text{FC}(x, w)\} \) results in a regular CNN, where Conv2D(x, w) is a 2D convolutional layer function and FC(x, w) is a fully connected layer function. If we select \( \Lambda = \{\text{Conv2D}(x, w_c \sim \mathcal{N}([\mu_c, \Sigma_c]), \text{FC}(x, w_l \sim \mathcal{N}([\mu_l, \Sigma_l]))\} \) with layer weights sampled from a corresponding Gaussian distribution, then the resulting network is a BBB CNN. Such neural network formulation allows to accurately describe all the discussed uncertainty estimation methods, as well as the proposed VNNs.

A. Variational Layer

We define a Variational Layer (VL) that takes an input \( x \) and weights \( w \) as
\[
VL(x, w) = \alpha_N(f(x, w)),
\]
\[
f(x, w) \sim \mathcal{N}\left(\alpha_\mu(L(x, \mu), \text{diag}(\alpha_\sigma(L(x, \sigma)))^2)\right),
\]
\[
w = (\mu, \sigma),
\]
where \( L(x, w) \) is a regular neural network layer, such as fully connected, convolutional or a recurrent layer. \( L(x, \mu) \) and \( L(x, \sigma) \) represent instances of the same layer with different values of parameters and corresponding activation functions \( \alpha_\mu(\cdot) \) and \( \alpha_\sigma(\cdot) \). The activation function \( \alpha_N(\cdot) \) can be used to apply nonlinearity to the randomly sampled values \( f(x, w) \). By selecting which of \( \alpha_\mu(\cdot), \alpha_\sigma(\cdot), \alpha_N(\cdot) \) are set to identity and which are set to actual activation functions (such as the Rectified Linear Unit (ReLU)) one can create networks that are described by different mathematical models. In the following, we show how different selections can lead to specific types of uncertainties, i.e. epistemic and aleatoric uncertainties [14].

B. Epistemic uncertainty

Fully connected and convolutional layers can be described as the operation \( L(x, \lambda) = W_\lambda x + b_\lambda \), where \( \lambda = (W_\lambda, b_\lambda) \), \( W_\lambda \) and \( b_\lambda \) are weights and biases of the layer, and a corresponding activation function \( \alpha(\cdot) \) can be applied to the output of \( L(x, \lambda) \).

Applying this formulation of a layer to a Variational Layer, together with selecting inner activations \( \alpha_\mu(\cdot) \) and \( \alpha_\sigma(\cdot) \) to
be identity functions, i.e., \( \alpha_\mu(L(x, \mu)) = W_\mu x + b_\mu \) and \( \alpha_\sigma(L(x, \sigma)) = W_\sigma x + b_\sigma \), the VL can be reformulated as
\[
VL(x, w) = \alpha_{N}(f(x, w)),
\]
\[
f(x, w) \sim N(W_\mu x + b_\mu + \text{diag}((W_\sigma x + b_\sigma)^2)),
\]
\[
w = (\mu, \sigma).
\]
Using the reparameterization trick \cite{Kingma2013} we can write \( f(x, w) \) as
\[
\epsilon \sim N(0, I),
\]
\[
f(x, w) = W_\mu x + b_\mu + \text{diag}((W_\sigma x + b_\sigma)^2) \epsilon,
\]
\[
= (W_\mu + \text{diag}(W_\sigma^2) x + (b_\mu + \text{diag}(b_\sigma^2)) \epsilon),
\]
\[
W \sim N(W_\mu, \text{diag}(W_\sigma^2)),
\]
\[
b \sim N(b_\mu, \text{diag}(b_\sigma^2)),
\]
\[
w = (\mu, \sigma).
\]
This means that a Variational Layer with inner activations \((\alpha_\mu, \alpha_\sigma)\) set to identity is identical to a regular layer with a distribution over weights, which is a BBB \cite{Gal2016} layer. However, in this case, the distributions for \(W\) and \(b\) are not independent, as they both come from the same draw of the random variable \(\epsilon\), which makes such VNN a statistically degraded version of BBB due to a stricter limit on the weight distribution.

C. Aleatoric uncertainty

Consider a Variational Layer with \(L(x, \sigma) = \Sigma, \Sigma \in \mathbb{R}\), which can be directly achieved by setting \(W_\sigma = 0, b_\sigma = \Sigma\) and setting the corresponding activation function \(\alpha_\sigma(\cdot)\) to identity. Using the same idea as in \cite{Gal2016}, we can write \(f(x)\) as
\[
\epsilon \sim N(0, I),
\]
\[
f(x) = \alpha_\mu(W_\mu x + b_\mu) + \Sigma \epsilon = L(x, \mu) + \epsilon_\Sigma
\]
\[
\epsilon_\Sigma \sim N(0, \Sigma I).
\]
In this formulation, \(\epsilon_\Sigma\) represents aleatoric uncertainty. Depending on the choice of weights and nonlinearities, the VL formulation can be simplified to a one that is described by either epistemic uncertainty (Section IV-B) or aleatoric uncertainty. This means, that without those simplifications, each Variational Layer incorporates both uncertainties.

D. Relation between VNNs and BNNs

BNNs consider a distribution over hyperparameters and weights, but the hyperparameters are usually set to a fixed point using a Dirac delta distribution to simplify the model, and the distribution over the weights is selected to be a relatively simple one, like the Bernoulli, Gaussian or Categorical distributions. VNNs do not consider a distribution over weights or hyperparameters (excluding the simplified VNN layers described in Section IV-B) and, therefore, VNNs are as close to BNNs as classical neural networks, which means that VNNs cannot be called Bayesian Neural Networks in a regular meaning of it. However, both BNNs and VNNs can be used to estimate uncertainties and can be formulated in a unified manner, which is shown in the next Section.

V. OUTPUT UNCERTAINTY ESTIMATION

Following \cite{Gal2016}, we consider a neural network \(F(x, w)\) with a parametric distribution over weights \(q_m(w)\). We assume the choice of \(q_m(w)\) in a form
\[
w = Q(m, z), \quad w \sim q_m(w), \quad z \sim p(z),
\]
where \(p(z)\) is a non-parametric distribution and \(Q(\cdot)\) applies a deterministic transformation, parametrized by \(m\), to a non-parametric random variable \(z\). Such formulation is suitable for every uncertainty estimation method described in Section III.

For BBB models, \(Q(\cdot)\) is defined as
\[
Q(m, z) = \mu + \sigma^2 z, \quad z \sim N(0, I), \quad m = (\mu, \sigma),
\]
where we break down a parametric Gaussian distribution \(N(\mu, \sigma I)\) into two parts: a parametric deterministic transformation \(z \rightarrow \mu + \sigma^2 z\) and a non-parametric random variable \(z \sim N(0, I)\).

Defining an epistemic index \(z \sim p(z)\) \cite{Gal2016}, we can formulate a deterministic neural network \(F_d(\cdot)\) function that takes a draw of a random non-parametric variable \(z\), instead of using \(F(\cdot)\) with a complex distribution over \(w\):
\[
F_d(x, m, z) := F(x, w), \quad w = Q(m, z), \quad z \sim p(z)
\]
With this formulation, a predictive distribution \(\mathbb{E}\) for fixed hyperparameters is defined as
\[
p(y|x, D) = \int p(y|x, w) q_m(w|D) dw = \int p(y|x, m, z) p(z) dz,
\]
\[
\mathbb{E}[y] = \int y p(y|x, D) dy \approx \frac{1}{T} \sum_i F_d(x, m, z_i),
\]
\[
\text{Cov}[y] = \int (y - E[y])(y - E[y])^T p(y|x, D) dy,
\]
\[
\approx \frac{1}{T} \sum_i (E[y] - F_d(x, m, z_i))(E[y] - F_d(x, m, z_i))^T.
\]

Expectation and variance are computed using Monte Carlo integration, which can be viewed as an approximation of \(p(z)\) with \(\sum_{i=0}^{T} \delta(z - z_i)\), \(z_i \sim p(z), \quad i = 1, \ldots, T\). Variance of the outputs is computed by taking main diagonal values of the \(\text{Cov}[y]\) representing the uncertainty of the model.

VNNs, despite not having a direct distribution over weights, can also be formulated as a deterministic function \(F_d(x, w, z)\) with a variational index \(z \sim p(z)\). In case of identity inner activations transforms into an epistemic index, and in case of constant \(L(x, \sigma)\) transforms into an aleatoric index. Otherwise, it is an index of a distribution that combines both aleatoric and epistemic uncertainties. Predictive distribution, expectation and variance for these cases are the same as in (13).

VI. UNCERTAINTY QUALITY ESTIMATION EXPERIMENTS

A recently proposed framework called Epistemic Neural Networks \cite{Gal2016} aims to provide a possibility to rank BNNs based on their ability to accurately estimate output uncertainty. This is done by first generating a synthetic dataset \(D_T = \{(x, y)_t\} \) for \(t \in [0, T - 1]\) for a simple regression task \(y = f(x) + \epsilon\), where \(y\) is an output scalar, \(z\) is an input data point with \(D_x\) number of dimensions, \(\epsilon\) is a random variable.
sampled from a Gaussian distribution $\mathcal{N}(0, \sigma^2)$ representing an aleatoric uncertainty. The dataset size $T$ is computed as $T = D_x \lambda$, meaning that with a higher dimensionality of $x$, the number of data points also increases.

The dataset is used to train a Neural Network Gaussian Process (NNGP) \cite{17}, and an uncertainty estimation model of interest. NNGP serves as an ideal probabilistic model for this data and a predictive distribution of a selected uncertainty estimation model should be as close as possible to the predictive distribution of the NNGP model. An additional dataset is used to evaluate the difference between those distributions by computing the KL-divergence between the true posterior $\mathcal{N}(\mu_{GP}, \sigma_{GP}^2)$ and a model predictive distribution $\mathcal{N}(\mu_B, \sigma_B^2)$. Lower values of KL-divergence represent better uncertainty quality for a selected model, and therefore can be used to rank different approaches for uncertainty estimation.

We implement VNNs inside the ENN’s JAX implementation \cite{18} to reproduce results for BBB \cite{4}, MCD \cite{5}, Ensemble \cite{6}, Hypermodel \cite{13} and compare them with VNN. We follow the original framework parameters and repeat experiments with the following options: $D_x \in \{10, 100, 1000\}$, $\lambda \in \{1, 10, 100\}$, and $\epsilon \in \{0.01, 0.1, 1\}$. Each model is trained with 10 different random seeds, and the resulting KL value is the average of individual runs. The average KL values across all experiment parameters are given in Fig. 1a and for the highest input dimension value $D_x = 1000$ are given in Fig. 1b.

VNN has better uncertainty quality than BBB and MCD, but it is outperformed by Hypermodel and Ensemble. This can be explained by the difference in BMA for Deep Ensembles and Variational Inference methods, as explained in \cite{2}. The weight probability distribution can be split into basins, where models sampled from the same basin are too similar and will describe the problem from the same point of view, resulting in multiple entries of actually identical model in the prediction voting. Deep Ensembles and Hypermodels avoid this problem by not having a single anchor point with small weight deviations, and therefore having high chances of converging trained models into different basins. This means that VNN has a higher chance than Ensemble to have its samples in a single basin, placing it in the same group as BBB and MCD. Additionally, with bigger data dimensionality $D_x$, MCD and BBB achieve worse results, while VNN, Ensemble and Hypermodel perform better, as can be seen by comparing results in Figs. 1a and 1b.

VII. IMAGE CLASSIFICATION EXPERIMENTS

We train the same methods, as in Section VII for image classification tasks on MNIST \cite{19} and CIFAR-10 \cite{20} datasets. To show the influence of model architecture on the performance, we use a set of architectures $\{F_i\}$ and train each method with the selected architecture $F$. We select a Base architecture to have 3 convolutional and 1 fully connected layers for MNIST, and 6 convolutional and 1 fully connected layers for CIFAR-10. Mini and Micro Base architectures have the same layer structure as the Base one, but a lower number of channels in each layer. MLP architecture consists of 3 fully connected layers. We also use Resnet-18 \cite{21} architecture for experiments on CIFAR-10. For each method, we train models with different hyperparameter values and select the best two models for comparison. The results of classification experiments are given in Fig. 2 and are roughly following the results of uncertainty quality estimation experiments.

VIII. CONCLUSIONS

In this work, we proposed a method for neural network uncertainty estimation called Variational Neural Networks and evaluated its quality within the Epistemic Neural Networks framework. Experiments show that, despite having similar properties of Bayesian Model Averaging as Monte Carlo Dropout and Bayes By Backpropagation, where sampled models are close, compared to Ensembles and Hypermodels, resulting in similar models’ points of view, VNNs achieve better uncertainty quality, which is retained when data dimensionality is increased, in contrast to Monte Carlo Dropout and Bayes By Backpropagation methods.

ACKNOWLEDGMENT

We thank Dr. Martin Magris for helpful discussions and feedback.
