Abstract

Multilevel linear models allow flexible statistical modelling of complex data with different levels of stratification. Identifying the most appropriate model from the large set of possible candidates is a challenging problem. In the Bayesian setting, the standard approach is a comparison of models using the model evidence or the Bayes factor. However, in all but the simplest of cases, direct computation of these quantities is impossible. Markov Chain Monte Carlo approaches are widely used, such as sequential Monte Carlo, but it is not always clear how well such techniques perform in practice. We present an improved method for estimation of the log model evidence, by an intermediate analytic computation of a marginal likelihood, integrated over non-variance parameters. This reduces the dimensionality of the Monte Carlo sampling algorithm, which in turn yields more consistent estimates. We illustrate this method on a popular multilevel dataset containing levels of radon in homes in the US state of Minnesota.

Keywords Bayesian model selection, marginal likelihood, Markov Chain Monte Carlo, model evidence, multilevel linear model

1 Introduction

Multilevel models provide a generalisation of linear models to settings in which the model parameters (or regression coefficients) are in some way stratified within the population \cite{1}. For example, individuals in the population may belong to a much smaller set of groups or clusters, and data may be available on the level of the individual and the level of the group. This concept can be arbitrarily extended to any number of groupings that exist within the population, either hierarchically or without nesting. A simple linear model is generally regarded as an inferior model choice in such situations as it neglects information inherently within the group structure. Instead, multilevel models explicitly model at each level of granularity. A wide variety of structures are possible, which raises an important question: how may we identify an optimal model structure from a number of competing hypothesised models? For example, should we include hierarchical structure, and should we prefer a multilevel model with varying intercepts or both varying slopes and intercepts? The answer to this question is generally context-specific, relating to the overarching goals of an analysis, e.g. inference or prediction, and any prior knowledge the researcher has about the problem. In conjunction with this, there exists an array of criteria that can be used to compare the suitability of two separate models. For example, in the frequentist setting, the mostly widely used is the Akaike information criterion (AIC) \cite{2}, though other approaches include false-discovery rate \cite{3} and likelihood ratio tests \cite{4,5}.

In this work, we instead focus on Bayesian approaches to model selection, where the usual strategy is to calculate the Bayes factor of two competing models. This is defined as the ratio of the model evidence for each model, where the model evidence is the likelihood integrated over all model parameters with respect to the prior. We refer to this as the model evidence instead of the marginal likelihood, in order to avoid confusion with a marginal likelihood that is integrated only over a subset of model parameters (nuisance parameters). A key advantage of using the model evidence for model comparison is that it implicitly discourages overfitting,
by penalising model complexity, since including additional parameters will increase the dimension of the parameter space to be integrated over. By way of contrast, the penalty on model complexity has to be artificially introduced in the AIC framework.

Unfortunately, the model evidence is generally an intractable integral, except in trivial cases. As a result, the Bayes factor must typically be estimated, either by directly approximating the integral as a sum, for instance using importance sampling [6] or sequential Monte Carlo [7], or by jointly estimating posterior probabilities of proposed models through approximate Bayesian computation (ABC) methods. In ABC methods, a hierarchical Markov Chain Monte Carlo (MCMC) sampling scheme alternates between two sampling steps, first across the indices denoting each model and then for model parameters of the current chosen model. This requires specification of prior probabilities for the individual models, in addition to priors for the parameters of each model. The relative acceptance frequencies in the chain for the model index then provides an approximation to the posterior probabilities for the models, which, alongside the given priors, allow an estimation of the Bayes factor that bypasses the need to estimate model evidence for each model. A key challenge in such an approach though, is to ensure sufficient mixing in the MCMC chain for the model index, since if the MCMC spends too long exploring only one model, the resulting extreme autocorrelation biases the posterior probability estimates. There are several approaches to this ABC framework, including reversible jump MCMC [8] and product-space MCMC [9]. In contrast to this imposed hierarchical structure of models, sequential Monte Carlo (SMC) can be run separately on each model, as a by-product of the algorithm is an estimate of the (log) model evidence. This is achieved by a combination of Metropolis-Hastings and importance sampling, in which the likelihood is optimised using a simulated annealing process. Whilst these Bayesian approaches are widely used, the estimates tend to suffer dramatically in high-dimensional settings, due to challenges in adequately sampling associated complex high-dimensional parameter spaces.

This motivates the approach to the estimation of Bayes factors that we take here, using partially-integrated marginal likelihoods instead of full likelihoods. Here we treat (potentially high-dimensional) non-variance parameters, such as the regression coefficients in the model, as nuisance parameters, and we analytically integrate these out with respect to appropriately-chosen priors, since this reduces the dimension of the problem. This reduces the full likelihood on all parameters to a marginal likelihood on only variance parameters. We can then estimate the model evidence by returning to sequential Monte Carlo, which yields improved results (reduces the bias and variance in such estimates) and typically improves computational efficiency.

We illustrate our technique using the Minnesota radon contamination dataset introduced by [1], and the various multilevel linear models that the authors originally proposed therein. This dataset contains measurements of the radon level in houses in the US state Minnesota, as well as predictors at the individual house level and at the county level. The grouping of houses within counties provides an inherent hierarchical structure. As radon is a carcinogen, identifying areas with higher concentrations of radon may be an important consideration in decision-making for homeowners and county authorities. This dataset has been used by several software packages to illustrate multilevel modelling approaches, such as in the Python module PyMC3 [10, 11].

2 Methods

As multilevel linear models are a generalisation of linear models, we can also view a simple linear model as the single-level case within the multilevel framework. For both clarity and computational reasons, we consider linear models and multilevel linear models separately here, first summarising notation and then providing the marginal likelihoods in each case, given suitable priors. Multilevel linear models are often interchangeably described as mixed models, where fixed and random effects are equivalent to the population-wide and group-specific variables. We use the vocabulary of multilevel linear models, to mirror the work of [1]. We provide open-access code for our work at [12]. In this code, we use PyMC3 for SMC sampling, given the full likelihoods and the marginal likelihoods that we have derived.

2.1 Definitions and notation

We first describe a linear model, in a setting with no multilevel structure. We use \( D \) to denote the data, which contains the observations \((y_i, x_i)\), for \( i = 1, \ldots, n \). The independent variables \( x_i \) are generally assumed
to be vector-valued, with dimension $d$, and we denote the corresponding regression coefficient vector as $\beta$. We assume this contains an intercept term (i.e. the first element of $x_i$ is 1 for all $i$). We focus on the subset of generalised linear models with normal distribution and identity link, which may be considered to be the simplest case for continuous observations, $y_i$. In a Bayesian setting, we require prior distributions for each model parameter, in this case the coefficient $\beta$ and variance parameter $\sigma^2$, to fully define a model. For a fixed-variance multivariate normal distribution likelihood, the conjugate prior for the mean is another multivariate normal distribution. Therefore, we choose to assign a prior of this form for $\beta$. In this section, we will not need specify a distributional form of the prior for $\sigma^2$ (though we later use an inverse-Gamma prior). A linear model, denoted $\mathcal{M}$, is:

$$\begin{align*}
\mathcal{M} : \ y_i = \beta^T x_i + \epsilon_i, \ & \epsilon_i \sim \mathcal{N}(0, \sigma_y^2) \\
\beta \sim \mathcal{N}(\mu, \Sigma), \ & \sigma^2 \sim P_{\sigma^2}
\end{align*}$$ (1)

The parameters of this linear model are denoted by $\theta = (\beta^T, \sigma^2)^T$. In addition to $\theta$, we have various hyperparameters, which include $\mu$, $\Sigma$ and any belonging to the unspecified distribution $P_{\sigma^2}$. Given our choice of multivariate normal prior for $\beta$, we could arbitrarily eliminate the mean $\mu$ by translating the data: $y_{ij} \mapsto y_{ij}' = y_{ij} + \mu^T x_{ij}$ (though we would need to factor this into the interpretation of any results). However, we generally assume the data have been normalised or centred and scaled for computational reasons. MCMC sampling tends to be more efficient with such preprocessed data, because of reduced autocorrelation in sampling chains, and a translation of the data to eliminate the $\mu$ may conflict with this. We assume independence of priors, so the prior for $\theta$ is the product of the individual priors for $\beta$ and $\sigma^2$. Given a model $\mathcal{M}$ with parameters $\theta$, we define the following:

- Likelihood, given parameters $\theta$: $p(D|\mathcal{M}, \theta)$
- Prior distribution function for $\theta$: $p(\theta|\mathcal{M}) = p(\beta|\mathcal{M})p(\sigma^2|\mathcal{M})$
- Posterior distribution function for $\theta$: $p(\theta|D, \mathcal{M}) = \frac{p(D|\theta, \mathcal{M})p(\theta|\mathcal{M})}{p(D|\mathcal{M})}$
- Marginal likelihood, integrated over $\beta$: $p(D|\mathcal{M}, \sigma^2) = \int_{\mathbb{R}^d} p(D|\mathcal{M}, \beta, \sigma^2)p(\beta|\mathcal{M})d\beta$
- Model evidence: $p(D|\mathcal{M}) = \int_{\theta} p(D|\mathcal{M}, \theta)p(\theta|\mathcal{M})d\theta$
- Akaike information criterion: $\text{AIC} = 2k - 2\max_{\theta} \log p(D|\mathcal{M}, \theta)$, where $k$ is the number of unconstrained parameters.

We now extend this notation to a multilevel linear model. We denote the data, $D$, as $(y_{ij}, x_{ij}, z_j)$, for the $i$th observation in group $j$, with $i = 1, \ldots, n_j$, $j = 1, \ldots, J$ and $\sum_n n_j = n$. As before, we focus on the normal-identity case, and we assume variables at the individual-level, $x_{ij}$, and group-level, $z_j$, are vector-valued, with corresponding $d$-dimensional individual-level and $m$-dimensional group-level regression coefficients, $\beta$ and $\alpha$ respectively. The multilevel framework contains a model for each level of the data, as below:

$$\begin{align*}
\mathcal{M} : \ y_{ij} = \beta^T x_{ij} + u_j + \epsilon_{ij}, \ & \epsilon_{ij} \sim \mathcal{N}(0, \sigma_y^2) \\
u_j = \alpha^T z_j + \eta_j, \ & \eta_j \sim \mathcal{N}(0, \sigma_n^2) \\
\beta \sim \mathcal{N}(\mu_\beta, \Sigma_\beta), \ & \alpha \sim \mathcal{N}(\mu_\alpha, \Sigma_\alpha), \ & \sigma_y^2 \sim P_{\sigma_y^2}, \ & \sigma_n^2 \sim P_{\sigma_n^2}
\end{align*}$$ (2)

We could straightforwardly introduce higher-level groups in analogous manner, though we will not elaborate on this here. It is also worth mentioning that the multilevel linear model can be rewritten as a single-level linear model with correlated errors [13]. For our purposes, it is more convenient to retain the multilevel formulation and, furthermore, to absorb the group-level variables, $z_j$, and group-level regression parameters, $\alpha$, into their individual-level counterparts, i.e. $(x_{ij}, z_j^T) \mapsto x_{ij}'$ and $(\beta^T, \alpha^T) \mapsto \beta^T$. The prior for the combined regression coefficient has mean $\mu_{\beta}', \mu_{\alpha}' = 0$ and block diagonal covariance matrix $\text{diag}(\Sigma_\beta, \Sigma_\alpha) = \Sigma$. Instead of the group-level $u_j$, we now model $u_j$ as a group-level deviation from the ‘population average’, and we consider the $J$-dimensional vector $\eta = (\eta_0, \ldots, \eta_J)$ as an additional nuisance variable to integrate out. We then rewrite the above model as:

$$\begin{align*}
\mathcal{M} : \ y_{ij} = \beta^T x_{ij} + \eta_j + \epsilon_{ij}, \ & \epsilon_{ij} \sim \mathcal{N}(0, \sigma_y^2), \ & \eta_j \sim \mathcal{N}(0, \sigma_\eta^2) \\
\beta \sim \mathcal{N}(\mu, \Sigma), \ & \sigma_y^2 \sim P_{\sigma_y^2}, \ & \sigma_\eta^2 \sim P_{\sigma_\eta^2}
\end{align*}$$ (3)
We now have model parameters \( \theta = (\beta^T, \sigma_y^2, \sigma^2) \), and model hyperparameters \( \mu, \Sigma \) and those from the unspecified distributions \( P_{\sigma_y^2} \) and \( P_{\sigma^2} \). The remaining quantities introduced above are much the same, except:

- **Model evidence:** 
  \( p(D|M) = \int_{\Theta \times \mathbb{R}^d} p(D|M, \theta) p(\theta|M) d\theta d\eta \)

- **Marginal likelihood, integrated over \( \beta \) and \( \nu \):** 
  \[
p(D|M, \sigma_y^2, \sigma^2) = \int_{\mathbb{R}^d} p(D|M, \eta, \beta, \sigma_y^2, \sigma^2) p(\eta|M, \sigma^2_y, \sigma^2) p(\beta|M) d\beta d\eta
  \]

Finally, we introduce a more general multilevel model, in which any regression coefficient may also vary by group, with a higher-level model for that variability, as opposed to just an intercept term. This model is:

\[
\mathcal{M} : \quad y_{ij} = \beta^T x_{ij} + \eta_j^T z_{ij} + \epsilon_{ij}, \quad \epsilon_{ij} \sim N(0, \sigma_y^2), \quad \eta_j \sim N(0, \Sigma_\eta(\nu)) \tag{4}
\]

\( \beta \sim N(\mu, \Sigma), \quad \sigma_y^2 \sim P_{\sigma_y^2}, \quad \nu \sim P_\nu \)

A key distinction here, which differentiates this from a linear model, is that \( \Sigma_\eta \) is an inherent variable of the model, rather than a fixed Bayesian hyperparameter. Also, as \( \Sigma_\eta \) is a symmetric positive-definite matrix, we parameterise this through a vector \( \nu \) instead of specifying the full matrix, for example \( \Sigma_\eta(\nu) = \nu I \), where \( I \) is the identity matrix. As before, we centre the group-level coefficients \( \eta_j \) by absorbing the ‘average’ into the \( \beta \) coefficient and, therefore, there can be an overlap between the variables included in \( z_{ij} \) and \( x_{ij} \).

We can compare two competing models for the data using the Bayes factor: \( BF_{mn} = p(D|M_m)/p(D|M_n) \). These may, for instance, contain different subsets of the independent variables or have different prior beliefs for the hyperparameters, though the data \( D \) must remain fixed, i.e. both models contain the same \( n \) individuals. The value of the Bayes factor indicates the strength of evidence for one model over the other. Interpretation is generally provided via tables proposed by [14] or [19].

### 2.2 Marginal likelihood for the linear model

We now provide marginal likelihoods for each model, with non-variance components integrated out with respect to the normal priors that we specified. For the linear model (1), this is:

\[
p(D|M, \sigma^2) = \int_{\mathbb{R}^d} p(D|M, \beta, \sigma^2) p(\beta|M) d\beta
\]

\[
= \int_{\mathbb{R}^d} \frac{1}{(2\pi)^{d/2}|\Sigma|^{1/2}} \exp \left( -\frac{1}{2} (\beta - \mu)^T \Sigma^{-1} (\beta - \mu) \right) \prod_i \frac{1}{\sqrt{2\pi \sigma^2}} \exp \left( -\frac{1}{2\sigma^2} (y_i - \beta^T x_i)^2 \right) d\beta
\]

\[
= \frac{1}{(2\pi)^{(d+n)/2}|\Sigma|^{1/2}\sigma^n} \int_{\mathbb{R}^d} \exp \left( -\frac{1}{2} \left[ (\beta - \mu)^T \Sigma^{-1} (\beta - \mu) + \frac{1}{\sigma^2} \sum_i (y_i - \beta^T x_i)^2 \right] \right) d\beta
\]

Rearranging the term in square brackets gives:

\[
(\beta - \mu)^T \Sigma^{-1} (\beta - \mu) + \frac{1}{\sigma^2} \sum_i (y_i - \beta^T x_i)(y_i - x_i^T \beta)
\]

\[
= \beta^T \left( \Sigma^{-1} + \frac{1}{\sigma^2} \sum_i x_i x_i^T \right) \beta - 2\beta^T \left( \Sigma^{-1} \mu + \frac{1}{\sigma^2} \sum_i x_i y_i \right) + \mu^T \Sigma^{-1} \mu + \frac{1}{\sigma^2} \sum_i y_i^2
\]

\[
= (\beta - \mu)^T \Sigma^{-1} (\beta - \mu) + \mu^T \Sigma^{-1} \mu + \frac{1}{\sigma^2} \sum_i y_i^2 - \mu^T \Sigma^{-1} \mu + \frac{1}{\sigma^2} \sum_i y_i^2
\]

where we define:

\[
\tilde{\Sigma}(\sigma^2) = \left( \Sigma^{-1} + \frac{1}{\sigma^2} \sum_i x_i x_i^T \right)^{-1}, \quad \tilde{\mu}(\sigma^2) = \tilde{\Sigma} \left( \Sigma^{-1} \mu + \frac{1}{\sigma^2} \sum_i x_i y_i \right)
\]
Therefore, we have the following marginal likelihood for the linear model:

\[
p(D|\mathcal{M}, \sigma^2) = \frac{|\Sigma|^{1/2}}{(2\pi\sigma^2)^{n/2}|\Sigma|^{1/2}} \exp\left(-\frac{1}{2} \left( \mu^T \Sigma^{-1} \mu + \frac{1}{\sigma^2} \sum_i y_i^2 - \hat{\mu}^T \Sigma^{-1} \hat{\mu} \right) \right)
\]  

(5)

where we use the following:

\[
\int_{\mathbb{R}^d} \frac{1}{(2\pi)^{d/2}|\Sigma|^{1/2}} \exp\left(-\frac{1}{2}(\beta - \hat{\mu})^T \Sigma^{-1}(\beta - \hat{\mu}) \right) d\beta = 1
\]

### 2.3 Marginal likelihood for a simple multilevel linear model

Now returning to the simple multilevel linear model (3), we perform a similar process, first integrating out \( \eta \) and then \( \beta \):

\[
p(D|\mathcal{M}, \sigma_y^2, \sigma_n^2) = \int_{\mathbb{R}^d} \int_{\mathbb{R}^J} \frac{1}{(2\pi)^{d/2}|\Sigma|^{1/2}} \exp\left(-\frac{1}{2}(\beta - \mu)^T \Sigma^{-1}(\beta - \mu) \right) \prod_j \frac{1}{\sqrt{2\pi\sigma_y^2}} \exp\left(-\frac{\eta_j^2}{2\sigma_y^2} \right) \times
\]

\[
\prod_{i,j} \frac{1}{2\pi\sigma_y^2} \exp\left(-\frac{(y_{ij} - \beta^T x_{ij} - \eta_j)^2}{2\sigma_y^2} \right) \ d\eta d\beta
\]

\[
= \frac{\sigma_n^2}{\sigma_y^2 |\Sigma|^{1/2}(2\pi)^{(\alpha+d)/2}} \int_{\mathbb{R}^d} \frac{1}{\sqrt{2\pi\sigma_n^2}} \exp\left(-\frac{\eta_j^2}{2\sigma_n^2} - \frac{1}{2\sigma_y^2} \sum_i (y_{ij} - \beta^T x_{ij} - \eta_j)^2 \right) d\eta_j \times
\]

\[
\prod_j \left[ \frac{1}{\sqrt{2\pi\sigma_n^2}} \int_{-\infty}^{\infty} \exp\left(-\frac{\eta_j^2}{2\sigma_n^2} - \frac{1}{2\sigma_y^2} \sum_i (y_{ij} - \beta^T x_{ij} - \eta_j)^2 \right) d\eta_j \right] d\beta
\]

We first consider the integral in square brackets, completing the square in \( \eta_j \) in the expression:

\[
\frac{\eta_j^2}{\sigma_n^2} + \frac{1}{\sigma_y^2} \sum_i (y_{ij} - \beta^T x_{ij} - \eta_j)^2 = \frac{\sigma_y^2 + n_j \sigma_n^2}{\sigma_y^2 + n_j \sigma_n^2} \left( \eta_j - \frac{\sigma_n^2}{\sigma_y^2 + n_j \sigma_n^2} \sum_i (y_{ij} - \beta^T x_{ij}) \right)^2 + \frac{1}{\sigma_y^2} \sum_i (y_{ij} - \beta^T x_{ij})^2 - \frac{1}{\sigma_y^2 \sigma_n^2 + n_j \sigma_n^2} \left( \sum_i (y_{ij} - \beta^T x_{ij}) \right)^2
\]

This gives:

\[
\frac{1}{\sqrt{2\pi\sigma_n^2}} \int_{-\infty}^{\infty} \exp\left(-\frac{\eta_j^2}{2\sigma_n^2} - \frac{1}{2\sigma_y^2} \sum_i (y_{ij} - \beta^T x_{ij} - \eta_j)^2 \right) d\eta_j
\]

\[
= \sqrt{\frac{\sigma_y^2}{\sigma_y^2 + n_j \sigma_n^2}} \exp\left(-\frac{1}{2\sigma_y^2} \left( \sum_i (y_{ij} - \beta^T x_{ij})^2 - \frac{\sigma_n^2}{\sigma_y^2 + n_j \sigma_n^2} \left( \sum_i (y_{ij} - \beta^T x_{ij}) \right)^2 \right) \right)
\]

Then, we perform a similar rearrangement with \( \beta \) as in the linear model case:

\[
(\beta - \mu)^T \Sigma^{-1}(\beta - \mu) + \frac{1}{\sigma_y^2} \sum_{i,j} (y_{ij} - \beta^T x_{ij})(y_{ij} - x_{ij}^T \beta) - \frac{1}{\sigma_y^2} \sum_j \left( \frac{\sigma_n^2}{\sigma_y^2 + n_j \sigma_n^2} \sum_i (y_{ij} - \beta^T x_{ij}) \right)^2
\]

\[
= (\beta - \hat{\mu})^T \Sigma^{-1}(\beta - \hat{\mu}) + \mu^T \Sigma^{-1} \mu + \frac{1}{\sigma_y^2} \sum_{i,j} y_{ij}^2 - \frac{1}{\sigma_y^2} \sum_j \left( \frac{\sigma_n^2}{\sigma_y^2 + n_j \sigma_n^2} \sum_i y_{ij} \right)^2 - \hat{\mu}^T \Sigma^{-1} \hat{\mu}
\]
where we define:

\[
\hat{\Sigma}(\sigma_y^2, \sigma_\eta^2) = \left( \Sigma^{-1} + \frac{1}{\sigma_y^2} \sum_{i,j} x_{ij} x_{ij}^T - \frac{1}{\sigma_y^2} \sum_{i} \left( \frac{\sigma_\eta^2}{\sigma_y^2 + n_j \sigma_\eta^2} \sum_{i} x_{ij} (\sum_k x_{kj}) \right) \right)^{-1}
\]

\[
\hat{\mu}(\sigma_y^2, \sigma_\eta^2) = \hat{\Sigma} \left( \Sigma^{-1} \mu + \frac{1}{\sigma_y^2} \sum_{i,j} x_{ij} y_{ij} - \frac{1}{\sigma_y^2} \sum_{j} \left( \frac{\sigma_\eta^2}{\sigma_y^2 + n_j \sigma_\eta^2} \sum_{i} y_{ij} (\sum_k x_{kj}) \right) \right)
\]

Finally, we get the marginal likelihood for the simple multilevel linear model:

\[
p(D|\mathcal{M}, \sigma_y^2, \sigma_\eta^2) = \frac{|\hat{\Sigma}|^{1/2}}{(2\pi \sigma_y^2)^{n/2}|\Sigma|^{1/2}} \prod_j \left( \frac{\sigma_\eta^2}{\sigma_y^2 + n_j \sigma_\eta^2} \right) \times 
\exp \left( -\frac{1}{2} \left( \mu^T \Sigma^{-1} \mu + \frac{1}{\sigma_y^2} \sum_{i} y_{ij}^2 - \frac{1}{\sigma_y^2} \sum_{j} \left( \frac{\sigma_\eta^2}{\sigma_y^2 + n_j \sigma_\eta^2} \sum_{i} y_{ij}^2 \right) - \hat{\mu}^T \hat{\Sigma}^{-1} \hat{\mu} \right) \right)
\]

(6)

2.4 Marginal likelihood for a general multilevel linear model

In the more general case, the steps are almost identical:

\[
p(D|\mathcal{M}, \sigma_y^2, \nu) = \int_{\mathbb{R}^d} \int_{\mathbb{R}^{m+d}} \frac{1}{(2\pi)^{d/2} |\Sigma|^{1/2}} \exp \left( -\frac{1}{2} (\beta - \mu)^T \Sigma^{-1} (\beta - \mu) \right) \times 
\prod_j \frac{1}{(2\pi)^{m/2} |\Sigma_\eta(\nu)|^{1/2}} \exp \left( \frac{1}{2} \eta_j^T \Sigma_\eta^{-1} (\nu) \eta_j \right) \times 
\prod_{i,j} \frac{1}{2\pi \sigma_y^2} \exp \left( -\frac{(y_{ij} - \beta^T x_{ij} - \eta_j^T z_{ij})^2}{2\sigma_y^2} \right) d\eta d\beta
\]

\[
= \frac{1}{\sigma_y^2 |\Sigma|^{1/2} |\Sigma_\eta(\nu)|^{m/2} (2\pi)^{(n+d+m)/2}} \int_{\mathbb{R}^{d+m+j}} \exp \left( -\frac{1}{2} (\beta - \mu)^T \Sigma^{-1} (\beta - \mu) \right) \times 
\exp \left( -\frac{1}{2} \sum_j \eta_j^T \Sigma_\eta^{-1} (\nu) \eta_j - \frac{1}{2\sigma_y^2} \sum_i \left( y_{ij} - \beta^T x_{ij} - \eta_j^T z_{ij} \right)^2 \right) d\eta d\beta
\]

Then:

\[
(\beta - \mu)^T \Sigma^{-1} (\beta - \mu) + \sum_j \eta_j^T \Sigma_\eta^{-1} \eta_j + \frac{1}{\sigma_y^2} \sum_i \left( y_{ij} - \beta^T x_{ij} - \eta_j^T z_{ij} \right)^2
\]

\[
= (\beta - \mu)^T \Sigma^{-1} (\beta - \mu) + \sum_j \left( \eta_j^T \left( \Sigma_\eta^{-1} + \frac{1}{\sigma_y^2} \sum_i z_{ij} z_{ij}^T \right) \eta_j - \eta_j^T \left( \frac{1}{\sigma_y^2} \sum_i z_{ij} (y_{ij} - \beta^T x_{ij}) \right) \right)
\]

\[
- \left( \frac{1}{\sigma_y^2} \sum_i (y_{ij} - \beta^T x_{ij}) z_{ij}^T \eta_j + \frac{1}{\sigma_y^2} \sum_i (y_{ij} - \beta^T x_{ij}) z_{ij} \eta_j \right)^T \eta_j \]

\[
= (\beta - \mu)^T \Sigma^{-1} (\beta - \mu) + \sum_j \left( (\eta_j - \mu_\eta,j)^T \Sigma_\eta^{-1} (\eta_j - \mu_\eta,j) + \frac{1}{\sigma_y^2} \sum_i (y_{ij} - \beta^T x_{ij})^2 - \mu_\eta,j^T \Sigma_\eta^{-1} \mu_\eta,j \right)
\]

\[
= (\beta - \hat{\mu})^T \hat{\Sigma}^{-1} (\beta - \hat{\mu}) + \sum_j \left( (\eta_j - \mu_\eta,j)^T \Sigma_\eta^{-1} (\eta_j - \mu_\eta,j) + \frac{1}{\sigma_y^2} \sum_i \eta_j^2 \right)
\]

\[
- \frac{1}{\sigma_y^2} \sum_j \left( \sum_i z_{ij} y_{ij} \right) \hat{\Sigma}_{\eta,j} \left( \sum_k z_{kj} y_{kj} \right) + \mu^T \Sigma^{-1} \mu - \hat{\mu}^T \hat{\Sigma}^{-1} \hat{\mu}
\]
In the context of linear model notation, we discard the group-level information, which we denote as follows:

\[ \hat{\mu}_{i,j}(\sigma_{y}^{2}, \nu) = \left( \sum_{i} \frac{1}{\sigma_{y}^{2}} \sum_{i,j} z_{ij} \hat{x}_{ij}^{T} \right)^{-1} \]

Finally, we get the marginal likelihood for the more general multilevel linear model:

\[ p(D|\mathcal{M}, \sigma_{y}^{2}, \nu) = \frac{1}{(2\pi\sigma_{y}^{2})^{n/2} |\Sigma|^{1/2} |\Sigma_{\eta}|^{1/2}} \prod_{j} |\hat{\Sigma}_{\eta,j}|^{1/2} \times \exp \left( -\frac{1}{2} \left( \mu^{T} \Sigma^{-1} \mu + \frac{1}{\sigma_{y}^{2}} \sum_{i,j} y_{ij}^{2} - \frac{1}{\sigma_{y}^{2}} \sum_{j} \left( \sum_{i} z_{ij} y_{ij} \right) \hat{\Sigma}_{\eta,j} \left( \sum_{k} z_{kj} y_{kj} \right) - \mu^{T} \Sigma^{-1} \mu \right) \right) \]

3 Results

We describe various models that fit within this framework, as proposed for the Minnesota radon contamination dataset by [12]. We deviate from their notation (e.g. renaming coefficients) for consistency with the above. Table 1 compares these models, in terms of the model evidence and the AIC, where we use SMC to estimate the model evidence using the full likelihoods and the derived marginal likelihoods. The hierarchical structure in this dataset is given in decreasing geographic granularity, with 919 individual measurements grouped within 371 ZIP codes and 85 counties, and data are available at the individual measurement-level and the county-level. This includes a measurement of the radon level on a logarithmic scale (standardised, with mean 0 and standard deviation 1), which we denote \( y_{ij} \); one individual-level indicator variable identifying the floor the measurement was taken on (0 for basement, 1 for first floor), which we denote \( t_{ij} \); and county-wide uranium levels on a logarithmic scale, which we denote \( v_{j} \) (also standardised). In each model, we adjust the intercept model matrix in \( x_{ij} \), to become \( x_{ij}^{T} = (1 - t_{ij}, t_{ij}) \), which we could equivalently rewrite as \( x_{ij}^{T} = (1_{t_{ij}=0}, 1_{t_{ij}=1}) \), where the indicator function, \( 1_{A} \), is equal to 1 if condition \( A \) is True and 0 otherwise. This means that we index by \( t_{ij} \) rather than including it as a binary variable. The primary reason for this is that we then express the same prior uncertainty for measurements that come from the basement floor and from the first floor, instead of increased uncertainty when \( t_{ij} = 1 \), as discussed in [11]. In the context of linear model notation, we discard the group-level \( j \) index, so that the index \( i \) runs over all individuals, \( i = 1, \ldots, n \). To denote the group \( j \) ownership for a particular individual \( i \), we instead use the index notation \( j[i] \). For example, if the individual 10 belongs to group 4, then \( j[10] = 4 \). The models suggested by Gelman and Hill include the following single-level linear models:

- **Complete pooling**: all counties are pooled to a single group, with a single intercept and gradient used for all counties, whilst the county-wide uranium levels are not included in the model. By ‘averaging’ the intercept term, this completely ignores any variation in the radon levels across counties. The model is:

\[ \mathcal{M}_{0} : y_{i} = a + bt_{i} + \epsilon_{i} = \beta^{T} x_{i} + \epsilon_{i}, \quad \beta^{T} = (a, b + a), \quad x_{i}^{T} = (1 - t_{i}, t_{i}), \quad \epsilon_{i} \sim \mathcal{N}(0, \sigma^{2}) \]

- **Complete pooling, with county-level variables**: as above, but with county-wide log uranium measurements included in the model. This at least contains some county-wide information, but does not directly model at the level of counties, as in the multilevel models.

\[ \mathcal{M}_{1} : y_{i} = a + bt_{i} + cv_{j[i]} + \epsilon_{i} = \beta^{T} x_{i} + \epsilon_{i}, \quad \beta^{T} = (a, b + a, c), \quad x_{i}^{T} = (1 - t_{i}, t_{i}, v_{j[i]}), \quad \epsilon_{i} \sim \mathcal{N}(0, \sigma^{2}) \]
• Unpooled intercept: each county has a separate intercept term. Although the county-level data is included via indicator variables that identify group membership, there is again no explicit intercept at the county-level. This is referred to as no pooling in the PyMC3 multilevel modelling notebook [11], though the coefficient for the floor/basement indicator variable is pooled across counties. We could also include the county-wide log uranium measurements here, but this will result in a non-identifiable model with collinear predictors.

\[ M_2 : y_i = a_{j[i]} + b_{j[i]}t_i + \epsilon_i = \beta^T x_i + \epsilon_i, \quad \epsilon_i \sim N(0, \sigma^2) \]

\[ \beta^T = (a_1 + b, \ldots, a_J + b, b), \quad x_i^T = (1_{(j[i]=1)}(1 - t_i), \ldots, 1_{(j[i]=J)}(1 - t_i), t_i) \]

• No pooling: each county is modelled completely independently of others, with separate intercepts and gradients. This will usually overfit the data, and perform relatively poorly for counties with limited data. In practice, 25 out of 85 counties have no measurements from the first floor, and we exclude those components in the vectors \( \beta \) and \( x_i \). The dimension of \( \beta \) is then 85 + 60 = 145.

\[ M_3 : y_i = a_{j[i]} + b_{j[i]}t_i + \epsilon_i = \beta^T x_i + \epsilon_i, \quad \epsilon_i \sim N(0, \sigma^2) \]

\[ \beta^T = (a_1 + b_1, \ldots, a_J + b_J, b_1, \ldots, b_J) \]

\[ x_i^T = (1_{(j[i]=1)}(1 - t_i), \ldots, 1_{(j[i]=J)}(1 - t_i), 1_{(j[i]=1)}t_i, \ldots, 1_{(j[i]=J)}t_i) \]

Where complete pooling and no pooling represent two extremes in model dimension within the linear model framework, [13] describe the multilevel model as akin to partial pooling, in which there is natural shrinkage of the non-pooled parameters (e.g. those featuring the index \( j[i] \)) to the mean (the ‘average’ in the complete pooling case). This can be seen as a compromise between the two linear model extremes. The multilevel models include the following:

• Partial pooling: county-wide variability is modelled directly as \( \eta_j \), a deviation from the ‘average’ intercept. This uses first multilevel model formulation as described in [13], with marginal likelihood given in [13].

\[ M_4 : y_{ij} = a + bt_{ij} + cv_j + \eta_j + \epsilon_{ij} = \beta^T x_{ij} + \eta_j + \epsilon_{ij}, \quad \epsilon_{ij} \sim N(0, \sigma_y^2), \quad \eta_j \sim N(0, \sigma_\eta^2) \]

\[ \beta^T = (a, b + a, c), \quad x_{ij}^T = (1 - t_{ij}, t_{ij}, v_j) \]

• Varying slopes and intercepts: in this model, we allow variability in both intercept and slope (i.e. the floor the measurement was taken on) across counties. This uses the more general multilevel model (described in [13], with marginal likelihood given in [13]). We evaluate a version of this that includes an off-diagonal (correlation) term in the \( \Sigma_\eta \) prior.

\[ M_5 : y_{ij} = a + bt_{ij} + cv_j + \eta_{j,0}(1 - t_{ij}) + \eta_{j,1}t_{ij} + \epsilon_{ij} = \beta^T x_{ij} + \eta_j^T z_{ij} + \epsilon_{ij} \]

\[ \epsilon_{ij} \sim N(0, \sigma_y^2), \quad \eta_j \sim N(0, \Sigma_\eta(\nu)) \]

\[ \beta^T = (a, b + a, c), \quad x_{ij}^T = (1 - t_{ij}, t_{ij}, v_j), \quad z_{ij}^T = (1 - t_{ij}, t_{ij}) \]

In each of these models, we set a multivariate normal prior \( N(0, I) \) on \( \beta \) and inverse-Gamma \( IG(3, 1) \) prior on each univariate variance component \( (\sigma^2, \sigma_\eta^2) \). In model \( M_5, \Sigma_\eta \) was parameterised by \( \nu = (\sigma^2_{\rho,0}, \sigma^2_{\rho,1}, \rho_\nu) \), where the first two components were diagonal terms, which had \( IG(3, 1) \) priors, \( \rho_\nu \) had a truncated normal prior on the interval \([-1, 1]\) with mean 0 and variance 1, and the non-zero off-diagonal term was \( \rho_{\nu,\sigma_{\nu,0}\sigma_{\nu,1}} \). The number of unconstrained model parameters, \( k \), in linear models is equal to the number of independent variables, which is the same as the dimension of the model evidence integral. In multilevel models, integration also happens over latent variables, while \( k \) is just number of independent variables plus the number of variance components.
### Table 1: Comparison of models for the Minnesota radon contamination dataset, using AIC and model evidence. The model evidence was computed using sequential Monte Carlo (SMC), using separately the marginal likelihood presented and the full likelihood. This was repeated for 8 random initialisations with 2000 draws at each step in SMC, and we present the mean and standard deviation of the model evidence from each run. The table also shows the number of model parameters, $k$, and the ranking (where smaller is better) of models for each approach.

| Model | $k$  | AIC rank | $\log p(D|M)$ rank | full likelihood $\log p(D|M)$ rank |
|-------|-----|----------|---------------------|-----------------------------------|
| $\mathcal{M}_0$ | 2544.17 | 6 | -1279.85 (0.04) | 6 |
| $\mathcal{M}_1$ | 3 2427.74 | 3 | -1224.12 (0.03) | 2 |
| $\mathcal{M}_2$ | 86 2490.28 | 4 | -1265.55 (0.04) | 4 |
| $\mathcal{M}_4$ | 145 2496.63 | 5 | -1270.67 (0.03) | 5 |
| $\mathcal{M}_5$ | 5 2425.21 | 2 | -1226.94 (0.04) | 3 |
| $\mathcal{M}_7$ | 7 2423.11 | 1 | -1220.69 (0.03) | 1 |

### 4 Discussion

Multilevel structure within data unlocks an increasing number of modelling choices for statisticians, though this additional modelling flexibility presents a challenge in deciding what and how to model the data. We present an approach to Bayesian model selection that estimates the model evidence using marginal likelihoods instead of full likelihoods. Since we are not interested in parameter inference, we can treat a subset of variables as nuisance variables that we analytically integrate out, which reduces the dimensionality of the model. By converting the problem in this manner, we limit the impact of this high-dimensionality, a key difficulty in sampling schemes for estimation of the desired quantities. As Table 1 shows, estimates of the model evidence using SMC and the marginal likelihood are consistent with AIC, following an almost identical ranking. In comparison with this, we believe there is likely a notable bias in the computation of the model evidence using the full likelihood, particularly in the explicitly multilevel models, whilst we also observe a significant increase in the variance of estimates when using the full likelihood in place of the marginal likelihood. Although static SMC is asymptotically unbiased in $n$ \[16\], it is sometimes unclear, when dealing with high-dimensional models, what constitutes an unbiased estimate in practice, as well as the number of samples needed for convergence. In high-dimensional settings, methods that directly estimate the model evidence integral may easily accumulate errors, leading to poor estimates. However, sampling using a highly-nonlinear low-dimensional marginal likelihood may in some instances be more computationally challenging than using the high-dimensional product of simpler likelihoods, rendering the marginal likelihood approach impractical due to computational constraints, without careful refactoring of code. We notice that both full and marginal likelihood methods are broadly similar in terms of computational cost for the linear model and simple multilevel linear model, but the marginal likelihood is more expensive for the more general multilevel model, which involves repeated computation and inversion of a large number of covariance matrices.

Bayesian model selection can be extended to a wide range of related problems fairly straightforwardly, such as variable selection and nested models (i.e. a comparison of two models where one is entirely contained with the other, as opposed to a nested structure in the data). It is worth emphasising a distinction between the model that best describes the data and the model that best achieves the research objective, which may not always coincide. For example, if the goal is to make inference on parameters associated with specific variables, then we should not exclude these variables on the basis of an evaluation of some model selection criteria. As George Box stated in one of the most well-known aphorisms in statistics \[17\]: ‘All models are wrong, but some are useful’. In a model selection problem, Bayesian approaches are particularly advantageous, because they factor prior uncertainty about model parameters in a way that naturally imposes a penalty on model complexity to prevent overfitting to the data. An important consideration is the choice of suitable priors for a given problem, to adequately balance previous scientific knowledge and information that the new data provides. Weakly informative priors are typically preferred to non-informative priors, which are often
not suitable if there is insufficient data available. It is worth emphasising that posteriori maximisation of the model evidence over prior hyperparameters is almost never appropriate in the context of an inference question, as this can be viewed as converting a priori fixed hyperparameters (part of the model definition) into tunable parameters of a completely different model (of models), under which the inference question may not remain as initially intended. Therefore, some caution should be taken to avoid ‘retro-fitting’ priors based on the data. However, with a priori justification, it is certainly possible to compare a discrete set of models that are identical except from different prior hyperparameters. For example, two statisticians may have wildly different prior beliefs based on previous research, and therefore propose separate prior distributions, which in turn can influence inference they make on model parameters, and we could ask whose model best describes the data. As always, prior predictive checking should be used to ensure priors give a reasonable coverage in predicted values.

We have limited this work to the simplest generalised linear models, with normal distribution and identity link (the canonical link function), choosing normal priors to mirror conjugate priors for a Gaussian likelihood. As any likelihood from the exponential family has a conjugate prior distribution, this analytic marginalisation can be similarly extended to generalised linear models under similarly chosen priors; for example, logistic regression (generalised linear model with Bernoulli distribution and logit link) with a beta conjugate prior on the Bernoulli parameter $p$. This allows the approach we have presented to be generalised to a much larger class of data and models.
