Abstract

We transform the problem of solving linear system of equations $A\mathbf{x} = \mathbf{b}$ to a problem of finding the right singular vector with singular value zero of the augmented matrix $C = \begin{pmatrix} A & \mathbf{b} \end{pmatrix}$, and present two quantum algorithms for solving this problem. The first algorithm solves the problem directly by applying the quantum eigenstate filtering algorithm with query complexity of $O(s\kappa \log(1/\epsilon))$ for a s -sparse matrix C , where κ is the condition number of the matrix A , and ϵ is the desired precision. The second algorithm uses the quantum resonant transition approach, the query complexity scales as $O[s\kappa + \log(1/\epsilon) / \log \log(1/\epsilon)]$. Both algorithms achieve the optimal query complexity in κ .

Introduction—Solving linear system of equations (LSE) is one of the fundamental problems in scientific computation. Given an $N \times N$ matrix A and a vector \mathbf{b} , the task is to find a vector \mathbf{x} such that $A\mathbf{x} = \mathbf{b}$. Solving high-dimensional LSE is expensive on a classical computer. Classical linear solvers can be categorized into the direct methods and the iterative methods [1]. The direct methods such as Gaussian elimination solve LSE with runtime scales as $O(N^3)$. There exists more efficient classical linear system solver that scales as $O(N^\nu)$ where $\nu \leq 2.373$ [2, 3], but it is difficult to utilize in practice due to numerical instability. The iterative methods show great advantages when they converge quickly, the iteration number is an indicator for the efficiency of these methods. E.g., for a symmetric positive-definite problem, the steepest descent method needs $O(\kappa \log(1/\epsilon))$ iterations and the conjugate gradient method needs $O(\sqrt{\kappa} \log(1/\epsilon))$, where κ is the condition number of the matrix A that is defined as the ratio between the largest and the smallest singular value of A , or $\|A\| \|A^{-1}\|$, and ϵ is the desired precision of the solution.

Quantum computer can provide an efficient way for solving the quantum linear system problems (QLSP), which aims to prepare a quantum state that is proportional to the solution vector of a given LSE, i.e., $|x\rangle = A^{-1}|b\rangle / \|A^{-1}|b\rangle\|$, where $\|\cdot\|$ denotes vector or matrix 2-norm. The quantum algorithms for solving the QLSP are either to apply the matrix inversion operator A^{-1} directly on the state $|b\rangle$ to obtain $|x\rangle$, e.g. the HHL algorithm [4, 5], or transform the LSE to an eigenvalue problem where the ground state of the problem Hamiltonian is the state $|x\rangle$ [6, 7]. For a brief review on recent progress on quantum algorithms for solving the QLSP, see [7] and references therein.

Recently, a quantum eigenstate filtering (QEF) algorithm [7] was proposed for solving the QLSP by combining with adiabatic quantum computing (AQC) or quantum Zeno effect (QZE). The QEF algorithm approximates a spectral projection operator by using the quantum signal processing (QSP) [8] method to project out the quantum state $|x\rangle$ from an initial state, without applying complex procedures of amplitude amplification or phase estimation. This algorithm achieves near optimal complexity of $O(s\kappa \text{poly} \log(\kappa) \log(1/\epsilon))$, where s is the sparsity of the matrix A . This is the best query complexity accomplished so far for solving the QLSP.

In this work, we show that the QLSP can be solved in a simpler way. We first prove that the solution vector to the LSE is proportional to the right singular vector of the augmented matrix $C = \begin{pmatrix} A & \mathbf{b} \end{pmatrix}$ with corresponding singular value 0. Then we transform the QLSP

to an eigenvalue problem of finding the eigenstate of a Hermitian matrix with eigenvalue 0. We apply two quantum algorithms for solving this problem. The first one applies the QEF algorithm to project out the desired eigenstate of the Hermitian matrix directly from an initial state whose overlap with the desired eigenstate is $O(1)$, without using techniques of AQC, QZE, amplitude amplification or phase estimation. This algorithm has query complexity of $O(s\kappa \log(1/\epsilon))$. The second one uses the quantum resonant transition (QRT) approach we developed for finding an eigenstate with known eigenvalue of a Hamiltonian [9–11]. The query complexity scales as $O[s\kappa + \log(1/\epsilon) / \log \log(1/\epsilon)]$. Both algorithms achieve the optimal query complexity in κ for solving the QLSP. In previous quantum algorithms, the complexity for preparing the state $|b\rangle$ and querying the matrix A are considered separately, while they are combined together in our work.

LSE and singular value decomposition.—The LSE $A\mathbf{x} = \mathbf{b}$ can be written in form of

$$C \begin{pmatrix} \mathbf{x} \\ -1 \end{pmatrix} = 0. \quad (1)$$

By performing singular value decomposition (SVD), we have $C = SDV^\dagger$, where S and V are unitary matrices of dimension N and $(N + 1)$, respectively, and $D = \begin{pmatrix} D' & \mathbf{0} \end{pmatrix}$, $D' = \text{diag}(\sigma_1, \dots, \sigma_N)$, and $\mathbf{0}$ is the zero column vector of dimension N , $\sigma_1 \geq \dots \geq \sigma_N$ are the singular values of the matrix C . Correspondingly, $\mathbf{s}_1, \dots, \mathbf{s}_N$ are column vectors of S , and $\mathbf{v}_1, \dots, \mathbf{v}_{N+1}$ are column vectors of V .

Theorem 1.—*Suppose x is the solution to the equation $Ax = b$, where A is an $N \times N$ nonsingular matrix, \mathbf{v}_{N+1} is the right singular vector corresponding to $C\mathbf{v}_{N+1} = \mathbf{0}$, where $C = \begin{pmatrix} A & \mathbf{b} \end{pmatrix}$, then the vector $\begin{pmatrix} \mathbf{x}^\mathbf{T}, -1 \end{pmatrix}^\mathbf{T}$ that satisfies Eq. (1) is proportional to the singular vector \mathbf{v}_{N+1} of the matrix C .*

Proof.—Since the rank of the matrix A is N , let $\sigma_{N+1} = 0$, the singular values of the matrix C satisfy $\sigma_1 \geq \dots \geq \sigma_N > \sigma_{N+1} = 0$. The matrix C can be written as $C = \sum_{i=1}^N \sigma_i \mathbf{s}_i \mathbf{v}_i^\dagger$. The column vectors $\mathbf{v}_1, \dots, \mathbf{v}_{N+1}$ of the unitary matrix V are orthogonal to each other, therefore to satisfy Eq. (1), the vector $\begin{pmatrix} \mathbf{x}^\mathbf{T}, -1 \end{pmatrix}^\mathbf{T}$ must be orthogonal to the vectors $\mathbf{v}_1, \dots, \mathbf{v}_N$, thus it is proportional to the vector \mathbf{v}_{N+1} , and $\begin{pmatrix} \mathbf{x}^\mathbf{T}, -1 \end{pmatrix}^\mathbf{T} = \frac{-\mathbf{v}_{N+1}}{\mathbf{v}_{N+1,N+1}}$, where $\mathbf{v}_{N+1,N+1}$ is the $(N + 1)$ -th component of the vector \mathbf{v}_{N+1} . \square

Let $\|A\| \leq 1$, we perform SVD for the matrix A , $\bar{S}^\dagger A \bar{V} = \text{diag}(\bar{\sigma}_1, \bar{\sigma}_2, \dots, \bar{\sigma}_N)$, where \bar{S} and \bar{V} are unitary matrices of dimension N , respectively. The singular values of the matrices

A and C satisfy the following relation [12]:

$$\sigma_1 \geq \bar{\sigma}_1 \geq \sigma_2 \geq \bar{\sigma}_2 \dots \geq \bar{\sigma}_N > \sigma_{N+1} = 0. \quad (2)$$

Then the energy gap between the singular states \mathbf{v}_{N+1} and \mathbf{v}_N is

$$\Delta = \sigma_N - \sigma_{N+1} \geq \Delta^* = \bar{\sigma}_N = \frac{1}{\kappa}. \quad (3)$$

Let $A' = \beta A$, where β is in the order of $O(\kappa)$. The solution to the equation $A'\mathbf{x}' = \mathbf{b}$ is $\mathbf{x}' = \mathbf{x}/\beta$. Following the above procedures, the matrix $C' = \begin{pmatrix} A' & \mathbf{b} \end{pmatrix}$ can be written as $C' = \sum_{i=1}^N \sigma'_i \mathbf{s}'_i \mathbf{v}'_i{}^\dagger$. The vector $\begin{pmatrix} \mathbf{x}'^T & -1 \end{pmatrix}^T$ is proportional to the vector \mathbf{v}'_{N+1} , and $\begin{pmatrix} \mathbf{x}'^T & -1 \end{pmatrix}^T = \frac{-\mathbf{v}'_{N+1}}{\mathbf{v}'_{N+1,N+1}}$, where $\mathbf{v}'_{N+1,N+1}$ is the $(N+1)$ -th component of the vector \mathbf{v}'_{N+1} . The first N components of the vector \mathbf{v}'_{N+1} is proportional to the solution vector \mathbf{x} of the LSE with a ratio of $-1/(\beta \mathbf{v}'_{N+1,N+1})$. Applying the same spectrum analysis for the matrices A' and C' , we have

$$\Delta' = \sigma'_N - \sigma'_{N+1} \geq \Delta'^* = \bar{\sigma}'_N = \beta \bar{\sigma}_N = O(1), \quad (4)$$

since β is in the order of $O(\kappa)$.

We construct a Hermitian matrix

$$B = \begin{pmatrix} 0 & C' \\ C'^\dagger & 0 \end{pmatrix}, \quad (5)$$

whose eigenvalues and the corresponding eigenstates are $\{\pm\sigma'_1, \dots, \pm\sigma'_N, \sigma'_{N+1} = 0\}$ and $\{(\mathbf{s}'_1, \pm\mathbf{v}'_1), \dots, (\mathbf{s}'_N, \pm\mathbf{v}'_N), (\mathbf{0}, \mathbf{v}'_{N+1})\}$, respectively. Then the problem of solving the LSE is transformed to finding the eigenstate $(\mathbf{0}, \mathbf{v}'_{N+1})$ of the matrix B with eigenvalue 0, and the gap between the eigenstate $(\mathbf{0}, \mathbf{v}'_{N+1})$ and the nearest eigenstate of B scales as $O(1)$.

Suppose $\|\mathbf{b}\| = 1$, the condition number of the matrix A is $\kappa = \bar{\sigma}_1/\bar{\sigma}_N = O(1/\bar{\sigma}_N)$. Then we have $\|\mathbf{x}\| = \|A^{-1}\| \|\mathbf{b}\| = O(\kappa)$ since $\|A^{-1}\| = 1/\bar{\sigma}_N$. For the LSE $A'\mathbf{x}' = \mathbf{b}$, we have $\|\mathbf{x}'\| = \beta^{-1} \|\mathbf{x}\| = O(1)$. Thus the overlap between the vectors $\begin{pmatrix} \mathbf{x}'^T & -1 \end{pmatrix}$ and $\begin{pmatrix} \mathbf{0} & 1 \end{pmatrix}$ is $O(1)$. The vector \mathbf{v}'_{N+1} is proportional to $\begin{pmatrix} \mathbf{x}'^T & -1 \end{pmatrix}$ up to a normalization factor, therefore the inner product between states $(\mathbf{0}, \mathbf{0}, 1)$ and $(\mathbf{0}, \mathbf{v}'_{N+1})$ of the matrix B is $|\mathbf{v}'_{N+1,N+1}|$ which is in order of $O(1)$.

In solving the QLSP, one needs to obtain the solution state that is proportional to the vector \mathbf{x} satisfying $A\mathbf{x} = \mathbf{b}$ efficiently from an initial state through some quantum procedures.

Usually it requires the initial state has large overlap with the solution state $|x\rangle$ of the QLSP. In the QEF algorithm, an AQC procedure is applied for preparing an initial state whose overlap with the solution state is $O(1)$. Then a state filtering function is applied on the initial state to project out the solution state efficiently. Such a procedure can also be realized through QZE by applying a sequence of QEF procedures following the same path as that of the AQC. In the QRT approach [9–11], one starts from an initial state and transform it to the desired eigenstate of a Hamiltonian through quantum resonant transitions. It also requires that the overlap between the initial state and the desired state to be $O(1)$ in order to run the algorithm efficiently.

In this work, we are to prepare the eigenstate $|\mathbf{v}'_{N+1}\rangle = (\mathbf{0}, \mathbf{v}'_{N+1})$ of the matrix B , where \mathbf{v}'_{N+1} is proportional to the vector $\left(\mathbf{x}'^T, -1\right)^T$ that contains the solution to $A\mathbf{x} = \mathbf{b}$ up to a factor. The gap between the eigenstate $|\mathbf{v}'_{N+1}\rangle$ and the nearest eigenstate of B scales as $O(1)$. We set the initial state of the quantum circuit as $|\mathbf{1}\rangle = (\mathbf{0}, \mathbf{0}, 1)$, whose overlap with the desired eigenstate $|\mathbf{v}'_{N+1}\rangle = (\mathbf{0}, \mathbf{v}'_{N+1})$ of the matrix B is $O(1)$, then both the QEF and the QRT algorithms can be run efficiently for solving the QLSP.

Solving QLSP through QEF.—The QEF algorithm projects out the desired eigenstate of a Hermitian matrix from an initial state by implementing an eigenstate-filtering function using the QSP method, which is a powerful quantum algorithm for implementing a polynomial function of matrices on a quantum computer with minimal number of ancilla qubits. We first use the block-encoding technique to encode the matrix B in a unitary matrix, then apply the QSP method to implement the QEF function to project out the eigenstate $|\mathbf{v}'_{N+1}\rangle$ of the matrix B from the initial state.

The matrix B is represented on an n -qubit quantum register, an $(m+n)$ -qubit unitary operator U_B is called a (α, m, ϵ) -block-encoding of the matrix B [13], if

$$\|B - \alpha(|0^m\rangle\langle 0^m| \otimes I_n) U_B (|0^m\rangle\langle 0^m| \otimes I_n)\| \leq \epsilon, \quad (6)$$

where I_n is an n -qubit identity matrix. Block-encoding of B can also be written in form of

$$U_B = \begin{pmatrix} B/\alpha & \cdot \\ \cdot & \cdot \end{pmatrix}, \quad (7)$$

where α scales as $O(\kappa)$ thus $\|B/\alpha\| \leq 1$. We have the following theorem:

Theorem 2 (*Polynomial eigenvalue transformation with definite parity via quantum signal processing* [7, 14]): *Let U_B be an $(\alpha, m, 0)$ -block-encoding of the Hermitian matrix B/α*

and $P \in \mathbb{R}[x]$ be a degree- l even or odd real polynomial and $|P(x)| \leq 1$ for any $x \in [-1, 1]$. Then there exists a $(1, m+1, 0)$ -block-encoding $U_{\tilde{\varphi}}$ of $P(B/\alpha)$ using l queries of U_B, U_B^\dagger , and $O((m+1)l)$ other primitive quantum gates.

Let $B/\alpha = \sum_{\lambda} \lambda |\lambda\rangle \langle \lambda|$, and define $\Pi := |0\rangle \langle 0|$ acting on an auxiliary qubit, and $\Pi_\phi := e^{i\phi(2\Pi-I)}$. For l is even, $U_{\tilde{\varphi}}$ is in form of [15]

$$U_{\tilde{\varphi}} = \prod_{k=1}^{l/2} \left(\Pi_{\varphi_{2k-1}} U_B^\dagger \Pi_{\varphi_{2k}} U_B \right) = \begin{pmatrix} P(B/\alpha) & \cdot \\ \cdot & \cdot \end{pmatrix}, \quad (8)$$

where $P(B/\alpha) = \sum_{\lambda} P(\lambda) |\lambda\rangle \langle \lambda|$ is a polynomial transform of the eigenvalues of B/α . The phase factors $(\varphi_1, \dots, \varphi_l)$ can be calculated efficiently on a classical computer [16–20]. The eigenvalue transform can be used to project out the desired eigenstate with known eigenvalue and filter out other unrelated states. For a Hermitian matrix with eigenvalue λ that is known to be separated from other eigenvalues by a gap $\Delta' > 0$, it has been shown that the following degree- $(l = 2k)$ polynomial

$$R_k(x; \Delta') = \frac{T_k\left(-1 + 2\frac{x^2 - \Delta'^2}{1 - \Delta'^2}\right)}{T_k\left(-1 + 2\frac{-\Delta'^2}{1 - \Delta'^2}\right)} \quad (9)$$

is an optimal polynomial for filtering out the unwanted eigenstates [7], where $T_k(x)$ is the k -th Chebyshev polynomial of the first kind. By using this polynomial in eigenvalue transform, the system can be projected onto the eigenspace corresponding to the eigenvalue λ .

The QEF algorithm for solving the QLSP is as follows: given the Hermitian matrix B , obtain its eigenstate $|\mathbf{v}'_{N+1}\rangle$ with known eigenvalue 0 that is separated from the nearest eigenstate of B by gap Δ' . We set the initial state of the quantum circuit as $|\mathbf{1}\rangle$, then apply the QEF algorithm to project out the eigenstate $|\mathbf{v}'_{N+1}\rangle$ of the matrix B/α with eigenvalue 0, while filtering out all other eigenstates. We have shown that the overlap between the states $|\mathbf{1}\rangle$ and $|\mathbf{v}'_{N+1}\rangle$ is $O(1)$. Therefore the eigenstate $|\mathbf{v}'_{N+1}\rangle$ can be obtained with success probability $O(1)$. The number of qubits required is $(n + m + 1)$.

The implementation of the algorithm requires querying the matrix B that contains the matrix C' which is composed of the matrix A' and the column vector $|b\rangle$ of the QLSP. If the matrix C' is s -sparse, we assume it can be accessed by oracles $O_{C,1}$ and $O_{C,2}$ as $O_{C,1}|j, l\rangle = |j, \nu(j, l)\rangle$, $O_{C,2}|j, k, z\rangle = |j, k, C'_{jk} \oplus z\rangle$, where $j, k, l, z \in [N+1]$. The oracle $O_{C,1}$ calculates $\nu(j, l)$ which is the row index of the l -th nonzero element in the j -th column of the matrix C' , and the oracle $O_{C,2}$ accepts the input (j, k) and returns C'_{jk} . This assumption is the same

as that of used in [5]. The oracles can be used to construct a $(s, n + 2, 0)$ -block-encoding of C' [5, 21]. The complexity of the QEF algorithm scales as $O((\alpha/\Delta') \log(1/\epsilon))$ [7]. Therefore the complexity of using the QEF algorithm for solving the QLSP scales as $O(s\kappa \log(1/\epsilon))$, since α scales as $O(\kappa)$ and Δ' scales as $O(1)$. In the case where the matrix A is s -sparse, and can be accessed by oracles $O_{A,1}$ and $O_{A,2}$ similar to the oracles $O_{C,1}$ and $O_{C,2}$, and the vector $|b\rangle$ can be prepared with an oracle O_b as $O_b|0\rangle = |b\rangle$, the matrix C' can be accessed by using oracles $O_{A,1}$ and $O_{A,2}$ to access the matrix A' and the oracle O_b to access the vector $|b\rangle$. Here, the complexity of preparing the initial state $|b\rangle$ and implementing the matrix A' is considered together in implementing the matrix C' .

Solving QLSP via QRT.—In Ref. [9–11], we proposed a quantum algorithm for finding an eigenstate with known corresponding eigenvalue of a Hamiltonian based on quantum resonant transitions. This algorithm can be applied for solving the QLSP by finding the eigenstate $|\mathbf{v}'_{N+1}\rangle$ of the Hermitian matrix B with the corresponding eigenvalue 0.

The algorithm requires $n + 1$ qubits with one probe qubit and an n -qubit register R representing the matrix B . The Hamiltonian of the algorithm is constructed as

$$H = -\frac{1}{2}\omega\sigma_z \otimes I_n + H_R + c\sigma_x \otimes I_n, \quad (10)$$

where

$$H_R = \varepsilon_0|1\rangle\langle 1| \otimes |\mathbf{1}\rangle\langle \mathbf{1}| + |0\rangle\langle 0| \otimes B, \quad (11)$$

and σ_x and σ_z are the Pauli matrices. The first term in Eq. (10) is the Hamiltonian of the probe qubit, the second term contains the Hamiltonian of the register R and describes the interaction between the probe qubit and R , and the third term is a perturbation. The parameter ε_0 is used as a reference point to the eigenstate $|\mathbf{v}'_{N+1}\rangle$ of the matrix B with eigenvalue 0, and $c \ll 1$.

The algorithm is run as follows:

i) Set the initial state of the $n + 1$ qubits as $|1\rangle|\mathbf{1}\rangle$, which is an eigenstate of H_R with eigenvalue ε_0 .

ii) Implement the unitary operator $U(t) = \exp(-iHt)$ by setting $\varepsilon_0 = -1$ and $\omega = 1$, therefore the condition for the resonant transition between the probe qubit and the transition between states $|\mathbf{1}\rangle$ and $|\mathbf{v}'_{N+1}\rangle$ is satisfied.

iii) Read out the state of the probe qubit.

As the resonant transition occurs, the system is approximately in state $\sqrt{1-p}|1\rangle|\mathbf{1}\rangle + \sqrt{p}|0\rangle|\mathbf{v}'_{N+1}\rangle$, where $p = \sin^2(ctd)$ is the decay probability of the probe qubit, and $c < \Delta'$ and $d = \langle \mathbf{1} | \mathbf{v}'_{N+1} \rangle$ is the overlap between the initial state $|\mathbf{1}\rangle$ and the eigenstate $|\mathbf{v}'_{N+1}\rangle$ of the matrix B . By performing a measurement on the probe qubit, if the probe decays to its ground state $|0\rangle$, it indicates that a resonant transition occurs and the system evolves to the state $|0\rangle|\mathbf{v}'_{N+1}\rangle$; otherwise if the probe qubit stays in state $|1\rangle$, it means that the register R remains in state $|\mathbf{1}\rangle$, then we repeat steps *ii*)-*iii*) until the probe qubit decays to its ground state $|0\rangle$.

The evolution time t of the QRT algorithm scales as $O(1)$ since the scaling of both d and Δ' thus c are in order of $O(1)$. The complexity of solving the QLSP by using the QRT approach is determined by Hamiltonian simulation of the algorithm $U(t) = \exp(-iHt)$. By applying a $(\alpha, m, 0)$ -block-encoding of H in a unitary matrix, the Hamiltonian simulation of H can be written as $U(t) = e^{-i(H/\alpha)\alpha t}$, and α scales as $O(\kappa)$. The optimal approach for Hamiltonian simulation is by applying the QSP algorithm, for which the complexity scales as $\Theta\left(\alpha t + \frac{\log(1/\epsilon)}{\log\left(e + \frac{\log(1/\epsilon)}{\alpha t}\right)}\right)$ [15]. Therefore in our algorithm, the complexity for solving the QLSP by using the QRT approach scales as $O[s\kappa + \log(1/\epsilon) / \log \log(1/\epsilon)]$, since t scales as $O(1)$ and α scales as $O(\kappa)$. The total number of qubits required in this algorithm is $(n + m + 2)$.

Discussion.—In this work, the problem of solving the linear system of equations is transformed to a problem of finding the eigenstate of a Hermitian matrix with eigenvalue 0. By modifying the form of the LSE, the energy gap between the desired eigenstate and its nearest eigenstate of the Hermitian matrix scales as $O(1)$. We also set an initial state whose overlap with the desired eigenstate of the Hermitian matrix is $O(1)$. Then we apply two quantum algorithms for solving the QLSP, respectively. The first algorithm applies the QEF algorithm directly on the initial state to project out the desired eigenstate of the Hermitian matrix without using the AQC or QZE, thus achieves a better query complexity of $O[s\kappa \log(1/\epsilon)]$ than that of the algorithm in [7]. The second algorithm uses the approach of QRT with query complexity of $O[s\kappa + \log(1/\epsilon) / \log \log(1/\epsilon)]$. Both algorithms scale linear in κ , which is essentially the optimal scaling since the dependence on κ cannot be made sublinear [4]. Querying the oracle that implements the matrix A and the oracle that prepares the state $|b\rangle$ are combined together in both algorithms.

In the algorithms, we obtain a state $|\mathbf{v}'_{N+1}\rangle$ that is proportional to the solution vector of

LSE with a ratio $-1/(\beta \mathbf{v}'_{N+1,N+1})$. The component $\mathbf{v}'_{N+1,N+1}$ can be obtained by calculating inner product between states $|\mathbf{v}'_{N+1}\rangle$ and $|\mathbf{1}\rangle$ through swap test [22]. The last component of the eigenstate $|\mathbf{v}'_{N+1}\rangle$ of the matrix C is irrelevant to the solution of the LSE, therefore the contribution from it in calculating expectation value of some operators or other applications can be set to zero through some adjustments.

The linear solver is a basic engine in engineering and scientific computing, and has wide applications in many areas. It paves a way for quantum machine learning, and acts as an important ingredient in linear regression, Bayesian inference, least-squares fitting, least squares support vector machine. The numerical solution of partial differential equations and ordinary differential equations is also built on it. After numerical discretization, such as the finite element method, finite difference method, or finite volume method, we usually need to solve a sparse linear system. The quantum algorithms we presented in this work for solving the QLSP can be used as a subroutine in solving these problems.
