We introduce a method that allows one to infer many properties of a quantum state—including non-linear functions such as Rényi entropies—using only global control over the constituent degrees of freedom. In this protocol, the state of interest is first entangled with a set of ancillas under a fixed global unitary, before projective measurements are made. We show that when the unitary is sufficiently entangling, a universal relationship between the statistics of the measurement outcomes and properties of the state emerges, which can be connected to the recently discovered phenomenon of emergent quantum state designs in chaotic systems. Thanks to this relationship, arbitrary observables can be reconstructed using the same number of experimental repetitions that would be required in classical shadow tomography [Huang et al. Nat. Phys. 16, 1050 (2020)]. Unlike previous approaches to shadow tomography, our protocol can be implemented using only global operations, as opposed to qubit-selective logic gates, which makes it particularly well-suited to analog quantum simulators, including ultracold atoms in optical lattices and arrays of Rydberg atoms.

**Introduction.**—The ability to control interactions in a many-body quantum system allows one to simulate and study other complex quantum systems of interest [1, 2]. In a universal quantum computer, where logical gates can be selectively applied to a few qubits at a time, one can in principle mimic the dynamics of any Hamiltonian [3]; however at present such devices are limited by their size and noisiness [4]. In contrast, analog quantum simulators—such as ultracold atoms in optical lattices [5, 6] and arrays of Rydberg atoms [7–10]—typically possess global rather than site-specific control, and as such are more tailored to synthesizing specific classes of Hamiltonian. Despite their limitations in terms of programmability, such platforms are often more scalable and less noisy than computationally universal devices, and have already been used to shed light on a wide variety of many-body quantum phenomena [11–20].

A key task in quantum simulation is to infer the properties of some many-body state once it has been prepared. In computationally universal devices, a particularly powerful technique known as shadow tomography can be employed for this purpose [21–23], wherein random unitary rotations are applied before projective measurements of each qubit are made (see also [24–26]). Using this scheme, many properties of the state can be simultaneously estimated using a single set of experimental data, and non-linear properties such as Rényi entropies can also be accessed. In contrast, due to the restricted set of pre-measurement unitaries that are available in analog quantum simulators, the observables that can be directly accessed therein (efficiently or otherwise) are much more limited.

In this paper, we bridge this gap by introducing a new protocol that allows one to simultaneously infer many properties of a state (including Rényi entropies, etc.) without needing to address each degree of freedom individually. Rather than applying inhomogeneous unitaries drawn randomly and compiled from few-qubit gates, we propose to apply some fixed deterministic global unitary $U$ to the system together with a set of ancillas, followed by measurements in the computational basis [see Eq. (1)]. The unitary need not be fine-tuned, and so can be native to the system in question, making our protocol particularly well-suited to analog quantum simulators. Importantly, our scheme offers the same performance guarantees as classical shadow tomography [23], meaning that the number of measurements needed to estimate a wide range of expectation values does not grow with system size.

We show that for generic choices of $U$ without conservation laws, a universal relationship between the distribution of measurement outcomes and expectation values of the state emerges. Specifically, the procedure becomes equivalent to making measurements of the state in bases drawn at random from a Haar ensemble. This equivalence is made precise later through our introduction of a construction called the tomographic ensemble: a probability distribution of wavefunctions that describes the overall measurement process [Eqs. (1, 2)]. For generic choices of $U$ integer moments of this ensemble agree closely with the Haar ensemble, i.e. an approximate quantum state design is formed [27, 28]. As a consequence of this, properties of the system density matrix can be reconstructed through appropriate post-processing of the measurement outcomes, namely simulation of the backwards time evolution $U^{-1}$ on a classical computer. Through matrix-product state methods and sparse matrices techniques, we show that the computational cost of this processing can be bounded, while still allowing reconstruction of observables with low relative error $\lesssim 1\%$.

The emergence of quantum state designs in this con-
text can be related to the recently introduced concept of ‘deep thermalization’, where state designs emerge in the projected ensemble of many-body quantum states \cite{29-34}. By adapting analytical arguments developed in that context, we rigorously establish the existence of state designs for particular representative cases. We supplement this with numerical evidence for generic choices of \( U \), which allows us to benchmark the full tomography procedure, and understand the effect of symmetries.

**Protocol.**—Our aim is to measure properties of some state of interest \( \rho_S \), which is prepared at the beginning of each run of the experiment in some register \( S \). For now, we consider systems of qubits, although similar considerations apply to more general setups. In addition, a set of ancilla qubits \( A \) is initialized in some predetermined state, which for convenience we assume to be a pure product state \( |0\rangle^{\otimes N_A} \) (this assumption is not strictly necessary). In our protocol, the system and ancilla qubits are jointly evolved using some fixed global unitary \( U \), which is generated by a (possibly time-dependent) Hamiltonian that can be readily simulated on the platform in question. Finally, all qubits are measured in the computational basis \( \{ |m\rangle \} \). This is repeated \( M \) times, resulting in a collection of \( M \) bitstrings \( m = m_1 m_2 \ldots m_N \), each of length \( N = N_S + N_A \). This protocol is illustrated in Fig. 1(a).

The bitstrings obtained in this experiment will be randomly distributed in a way that depends on both \( U \) and \( \rho_S \). For a given choice of \( U \), it may or may not be possible to infer properties of \( \rho_S \) using these data. As a simple example, suppose the evolution is trivial \( U = I \), in which case we are just measuring \( \rho_S \) in the computational basis. Clearly, diagonal matrix elements of \( \rho_S \) can be determined with enough data, but the measurement outcomes contain no information about off-diagonal coherences. However, when \( U \) is nontrivial, the ancilla measurement outcomes can in principle contain more information about \( \rho_S \). We will show that for generic choices of \( U \), any observable can be inferred from the distribution of measurement outcomes \( m \), and—crucially—that the number of experimental repetitions \( M \) and amount of classical computation required to estimate most observables of interest can be bounded, in the same spirit as classical shadow tomography \cite{23} (see the supplement \cite{35}).

The above claim can be more precisely specified using the formalism of positive operator-valued measures (POVMs). Most generally, any measurement scheme on a state \( \rho_S \) whose possible outcomes are indexed by \( m \) can be captured by a set of positive Hermitian operators \( F_m \geq 0 \), known as a POVM, chosen such that the probability of obtaining outcome \( m \) is \( \mathbb{P}(m|\rho_S) = \text{Tr}[F_m \rho_S] \). The constraint that all probabilities should sum to unity implies \( \sum_m F_m = I_S \). For the above protocol, the POVM operators are given by

\[
F_m = (I_S \otimes |0\rangle_A) U^\dagger |m\rangle \langle m| U (I_S \otimes |0\rangle_A).
\]

For the time being, we have assumed that the initial state of the ancilla is pure and the evolution is unitary. Therefore, \( F_m \) are proportional to rank-1 projectors \( F_m = d_S q_m |\phi_m\rangle \langle \phi_m| \), where \( q_m = \mathbb{P}(m|I_S/d_S) = \text{Tr}[F_m]/d_S \) are the outcome probabilities for the maximally mixed state \( I_S/d_S \). The constraint that all probabilities should sum to unity implies \( \sum_m F_m = I_S \). For the above protocol, the POVM operators are given by

\[
F_m = (I_S \otimes |0\rangle_A) U^\dagger |m\rangle \langle m| U (I_S \otimes |0\rangle_A).
\]

For the time being, we have assumed that the initial state of the ancilla is pure and the evolution is unitary. Therefore, \( F_m \) are proportional to rank-1 projectors \( F_m = d_S q_m |\phi_m\rangle \langle \phi_m| \), where \( q_m = \mathbb{P}(m|I_S/d_S) = \text{Tr}[F_m]/d_S \) are the outcome probabilities for the maximally mixed state \( I_S/d_S \). The constraint that all probabilities should sum to unity implies \( \sum_m F_m = I_S \). For the above protocol, the POVM operators are given by

\[
F_m = (I_S \otimes |0\rangle_A) U^\dagger |m\rangle \langle m| U (I_S \otimes |0\rangle_A).
\]
ble introduced here, we draw upon insight from the recently studied concept of the projected ensemble, which is defined as follows: Given a bipartite wavefunction $|\Psi^S_A\rangle$, one can consider measuring all qubits in $A$ in some preselected basis $\{ |m\rangle_A \}$, usually chosen to be a product basis. The projected ensemble is the probability distribution of post-measurement states $|\phi_m\rangle_S = (|S\rangle \otimes |m\rangle_A) |\Psi^S_A\rangle / \sqrt{p_m}$, conditioned on the random outcome of the measurement $m$, which occurs with probability $p_m = (|S\rangle \otimes |m\rangle_A) |\Psi^S_A\rangle$. As above, integer moments of this ensemble can be constructed according to Eq. (2).

In Refs. [29, 31, 32], it was shown that for a wide variety of generic many-body states, the projected ensemble forms an approximate quantum state design when $A$ is sufficiently large. An example that is closely connected to our setup is when $|\Psi_m\rangle = U |0\rangle$, where $|0\rangle$ product state and $U$ is a sufficiently entangling unitary. In this case, the construction of the projected and tomographic ensembles for a given unitary $U$ closely resemble one another, differing only in the region $S$. Note that there are some key differences between the two—most importantly the tomographic ensemble always forms a 1-design thanks to conservation of probability, whereas the same is not guaranteed in the projected ensemble.

Nevertheless, using this analogy we can adapt previous proofs that establish the existence of $k$-designs in the projected ensemble for certain classes of $U$, and we find that the same holds for the tomographic ensemble. Specifically, when $U$ is a single unitary drawn from the Haar ensemble (a dual-unitary circuit run over $t$ timesteps), the tomographic ensemble forms an approximate (exact) state design—see the Supplemental Material [35].

To demonstrate that the same occurs for generic unitaries $U$, we must turn to numerical simulations. As figure of merit, following Ref. [29], we employ the trace distance $\Delta := \frac{1}{2} \| \mathcal{E}(k) - \mathcal{E}_\text{Haar}(k) \|_1$, which quantifies how far the tomographic ensemble is from being a $k$-design ($\|C\|_1 = \text{Tr}[\sqrt{CC^\dagger}]$ is the trace norm). We study dynamics generated by Hamiltonians of the form $H(t) = \sum_j X_j X_{j+1} + h_x(t) X_j + h_y(t) Y_j$, which approximates the native dynamics of Rydberg atom quantum simulators [17]; here $X_j, Y_j, Z_j$ are Pauli matrices for qubit $j$. In certain parameter regimes, this model is known to give rise to fast scrambling of information [36–39]. Furthermore, when the fields $h_x(t)$ and $h_y(t)$ are time-dependent, there are no conserved quantities (including energy density), and we find that this encourages a rapid approach to $k$-design. In particular, we find that Floquet evolution works well, with $h_x = 0.8$, and $h_y(t)$ toggling periodically between 0.9 for $t \in [n, n + 0.5)$ and 1.8 for $t \in [n - 0.5, n]$, with $n \in \mathbb{Z}$. In the following, the system qubits are located at the centre of a chain with open boundary conditions.

The behaviour of the trace distance for $k = 2$ as a function of time is shown in Fig. 2 for various different $N_A$.

We see approximately exponential decay with time, until a plateau is reached. The value of this plateau is close to the average trace distance that one obtains by replacing $|\phi_m\rangle$ with $2^N$ independently sampled Haar-random wavefunctions, indicating that the states making up the tomographic ensemble are effectively quasirandom. Accordingly, the plateau trace distance scales as $\sim 1/\sqrt{2^N}$. This behaviour is qualitatively similar behaviour to that seen in the projected ensemble of wavefunctions generated from non-energy-conserving dynamics [33].

Extracting properties of the state.—Having established that the POVMs generated from our protocol generically form quantum state designs, we now describe how this property can be leveraged to perform shadow tomography of a state $\rho_S$.

For a fixed unitary $U$, the distribution of measurement outcomes $p_m$ depends on the state $\rho_S$ through the POVM operators (1). It will be useful to treat operators on $S$ as vectors over a $2^N$-dimensional space, denoted using double angled brackets $|O\rangle$ and equipped with the Hilbert-Schmidt inner product $\langle O | O' \rangle = \text{Tr}[O^\dagger O']$. Similarly, the outcome distribution can be written as a $2^M$-dimensional vector $|p\rangle = \sum_m p_m |m\rangle$ where $|m\rangle$ is an orthonormal basis for $\mathbb{R}^{2^N}$, i.e. $\langle m | m' \rangle = \delta_{m,m'}$. One can then define a completely positive linear map, which we call the POVM channel

$$F = \sum_m |m\rangle \langle F_m|$$

such that the outcome probabilities are given by $|p\rangle = F |\rho_S\rangle$.

A given expectation value $\langle O \rangle = \text{Tr}[O \rho_S]$ can be inferred from the distribution of outcomes if there exists a dual vector $\omega_O = \sum_m w_m |m\rangle$ such that $\langle w_O | F = \langle O \rangle$. Provided that such a vector exists, one can construct an estimator $\hat{\theta}_O$ for $\langle O \rangle$ from a series of experimentally
obtained outcomes \{\hat{m}^{(r)}\} (r = 1, \ldots, M labels each repetition, and we use hats to denote random variables). In this work, we employ a linear estimation scheme \(\hat{\theta}_O = M^{-1} \sum_{r=1}^M (w_O|\hat{m}^{(r)}\rangle\langle\hat{m}^{(r)}|)\), for simplicity. It is straightforward to show that \(\hat{\theta}_O\) is an unbiased estimator of \(\langle O\rangle\), i.e. \(\mathbb{E}_m \hat{\theta}_O = \langle O\rangle\).

Returning to our example of trivial evolution \(U = \mathbb{I}\), we have \(F_m = |m_S\rangle\langle m_S|\), where \(m_S\) is the part of the bitstring \(m\) corresponding to qubits in \(S\). Purely off-diagonal operators, e.g. the Pauli operator \(X_j\), are right-annihilated by \(F\), and hence we cannot find a dual vector satisfying \(\langle w_O|F = \langle X_j|\). Thus, information about expectation values such as \(\langle X_j\rangle\) is lost. Contrastingly, diagonal operators \(O = \text{diag}(o_m)\) can be reconstructed by simply choosing \(\langle w_O| = \sum_m o_m|m\rangle\).

If, on the other hand, there are no nonzero operators annihilated by \(F\), i.e. rank(\(F\)) = \(d_S^2\), then one can find a left inverse \(G\) satisfying \(GF = \mathbb{I}\). Such a POVM is called informationally complete. An appropriate dual vector for any observable \(O\) can be constructed as \(\langle w_O| = \langle O|G\rangle\), and hence all observables can be inferred from measurement outcome statistics. Since \(G\) is non-unique in general, naturally we wish to find an expression that minimizes the variance \(\text{Var} \hat{\theta}_O = M^{-1}(\sum_m p_m w_m^2 - \langle O\rangle^2)\). This quantity depends on the state \(\rho_S\) itself through the probabilities \(p_m\), which in principle is not known in advance. Following Ref. [40], to reflect our lack of a priori knowledge of \(\rho_S\) we first average over all unitarily equivalent states, and then minimize this averaged variance. Defining the normalized channel \(\tilde{F} = \sum_m |m\rangle\langle F_m|\), the optimal choice is \(\langle w_O^*| = \langle O|\tilde{G}^*\rangle\), with the inverse map given by

\[
\tilde{G}^* := M^{-1}\tilde{F}^\dagger \quad \text{where} \quad M := \sum_m \text{Tr}[F_m]\langle \tilde{F}_m|\tilde{F}_m\rangle\langle\tilde{F}_m|.
\]

(See the supplement for a proof [35].) The map \(M\) is a superoperator mapping the space of operators on \(S\) to itself. It has full rank whenever \(F\) is informationally complete, and therefore has a unique inverse.

At this point, recalling that the POVM operators \(1\) are rank-1 projectors, we notice that the superoperator \(M\) is equivalent to the second moment of the tomographic ensemble \(\mathcal{E}^{(2)}\), Eq. (2). (Specifically, their matrix elements are related by \(\langle E_{ij}|M|E_{kl}\rangle = d_S\langle k|\mathcal{E}^{(2)}|j\rangle\), where \(E_{ij} := |i\rangle\langle j|\), with \(|i\rangle\), \(|j\rangle\) denoting states of \(S\).) A similar observation regarding the role of 2-designs in full quantum state tomography was also pointed out in Ref. [40]. Here, having established that state designs generically appear in our protocol, we can replace \(M\) with its universal 2-design form \(M = (\mathbb{I} + |\langle\mathbb{I}|\rangle)/(d_S + 1)\), which has an inverse

\[
M^{-1}|O\rangle = (d_S + 1)|O\rangle - \text{Tr}[O]|\mathbb{I}\rangle.
\]

Readers familiar with the formalism of classical shadow tomography will recognize \(M\) as the same channel that describes measurements after random Clifford rotations \([23, 35]\).

To determine whether a given expectation value can be estimated using a reasonable number of repetitions \(M\), we must calculate the variance of the optimal estimator \(\text{Var} \hat{\theta}_O = \sum_m \text{Tr}[F_m\rho_S\langle w_{\bar{O}}|m\rangle^2\). Using \(\langle w_{\bar{O}}|m\rangle = \langle \mathcal{M}^{-1}|\bar{O}|F_m\rangle\), we find

\[
\text{Var} \hat{\theta}_O = \frac{1}{M} \text{Tr}\left[\left(\rho_S \otimes \mathcal{M}^{-1}|\bar{O}\rangle\langle\bar{O}|\right)\left(\sum_m F_m \otimes \tilde{F}_m^2\right)\right]
\]

(6)

The factor in rounded brackets we identify as the third moment, \(\mathcal{E}^{(3)}\) in Eq. (2). Therefore, if the tomographic ensemble forms a 3-design, as we expect for generic unitaries \(U\), then the variance (6) will be the same as for any other POVM for which the \(F_m\) form a 3-design. One such POVM arises in classical shadow tomography with random global Clifford unitaries [35]. Therefore we can conclude that our scheme can be used to estimate expectation values of \(\rho_S\) using the same number of repetitions \(M\) as one would need when doing ordinary classical shadow tomography. The dependence of the variance on the observable in question is well-characterized in Ref. [23]: observables with bounded spectral norm \(|\mathcal{O}|\leq 1\) can be efficiently estimated for any system size \(N_S\).

To summarise, we have shown that the inverse map (4) can be used to construct estimators of expectation values, and that the map \(\mathcal{M}^{-1}\) can be replaced by its universal form (5) when the tomographic ensemble forms an approximate 2-design. The deviation from the 2-design will govern the systematic error \(\mathbb{E}\hat{\theta}_O - \langle O\rangle\) of any such estimator, while the \(k = 3\) moments \(\mathcal{E}^{(3)}\) determine the variance via (6). It is evidently favourable to have the tomographic ensemble as close to a 2- and 3-design as possible, which occurs for generic chaotic evolution as we saw above.

**Benchmarking the protocol.**—We now provide numerical simulations of our full protocol, including the joint evolution of the system and ancillas, the sampling of measurement outcomes, and the reconstruction of observables. We test our measurement scheme on a family of two-qubit target states \(\rho_2(\alpha) = \alpha|\text{EPR}\rangle\langle\text{EPR}| + (1 - \alpha)|00\rangle\langle00| + |11\rangle\langle11|)/2\), where \(|\text{EPR}\rangle = (|00\rangle + |11\rangle)/\sqrt{2}\) is an Einstein-Podolsky-Rosen state. The coherence parameter \(\alpha \in [0, 1]\) allows us to interpolate between fully dephased (\(\alpha = 0\)) and pure (\(\alpha = 1\)) EPR pairs. For the purpose of demonstration, the observable we choose to reconstruct is the fidelity with the EPR state \(\text{Tr}[\rho_2|\text{EPR}\rangle\langle\text{EPR}|]\), whose true value is \((1 + \alpha)/2\).

In one set of simulations, we generate \(U\) from Floquet evolution using the tilted-field Ising model as a generating Hamiltonian, as before. In a second set, we also add some randomness to \(U\)—that is, for each repetition \(r\) we sample \(U^{(r)}\) from a distribution of unitaries, which are
still generated via global Hamiltonian evolution. Then, $U^{(r)}$ is used in the joint system-ancilla evolution, and in the construction of estimators. The effect of introducing randomness is to reduce any small systematic error in the protocol coming from deviation of the tomographic ensemble from a 2-design; see the Supplement for details [35]. To construct random unitaries $U^{(r)}$, for each time interval of length $\tau = 0.5$, we sample each field component $\hat{h}^{x,y}$ independently from a normal distribution with zero mean and standard deviation $\sqrt{2}$.

In the case of the deterministic protocol, larger $N_A$ is required to reach acceptably small systematic errors. For this purpose we employ MPS methods using ITensor [41, 42]. To mimic the evolution of the quantum device, we use tDMRG with unbounded bond dimension, retaining singular values up to a tolerance $\epsilon = 10^{-11}$. The backwards time evolution $U^\dagger |m\rangle$ required to construct the estimator via Eq. (4) must be classically simulated even in actual experiments; therefore we truncate the bond dimension to a maximum value of $\chi_{\text{back}}$ to keep computational costs bounded. In the randomized protocol, small values of $N_A$ already yield good results, and exact diagonalization can be used.

In Fig. 3, we plot estimations of the fidelity for various different $\alpha$ and tomography schemes, using $M = 5 \times 10^3$ repetitions each. We see closer agreement with the true fidelity as the time of evolution $t$ is increased, and when randomness is introduced. Furthermore, in the semi-randomized protocol we find that the systematic error remains small even when fewer ancillas are used, compared to the deterministic case. The errors we find are approximately agnostic to the coherence $\alpha$ of the target state $\rho_S$, and are on the order of 1%.

**Classical computations.**—As in classical shadow tomography, the estimation of expectation values from experimental data requires a certain amount of classical post-processing, the complexity of which we wish to bound. Specifically, when an outcome $m$ is observed we must evaluate $w_m = \langle O | S_\alpha | m \rangle$, which requires computation of the backwards time evolution $U^\dagger | m \rangle$.

When the number of system qubits $N_S$ is $O(1)$, the evolution time required to obtain an approximate state design is also $O(1)$, and hence efficient matrix product state techniques can be used even for large $N_A$. For tomography of many-body states, the present strategy must be modified, since the time of evolution required to reach a state design grows with $N_S$. Instead of evolving all system qubits with a single collection of ancillas, one can instead block the system into $n$ groups of $N_S/n = O(1)$ qubits, and evolve each block jointly with a separate collection of ancillas $A_j$ under a unitary $U_j$, where $j = 1, \ldots, n$. This scheme, illustrated in Fig. 1(b), yields POVM operators $F_{m_1,\ldots,m_n} = \bigotimes_{j=1}^{n} F_{m_j}^{(j)}$, where each $F_{m_j}^{(j)}$ is of the form (1). The tomographic ensemble for each separate block reaches an approximate 3-design in an $O(1)$ time, allowing $F_{m_1,\ldots,m_n}$ to be evaluated efficiently using matrix product methods as before. The tradeoff is that $M^{-1}$ must be replaced by a $n$-fold tensor product of (5), and this will affect how the estimator variance (6) depends on the observable $O$. By analogy to shadow tomography with random local Pauli measurements [23], observables with support on a small number of blocks will still be accessible using a reasonable number of repetitions $M$, regardless of how big $S$ is; we prove bounds on the variance in the supplement that confirm this [35].

Note that one could in principle compute the map $M^{-1}$ without using the universal 2-design form (5), which would eliminate any systematic error in estimation. However, this is only feasible for a small number of ancillas $N_A$, since $2^{N_S+N_A}$ separate terms must be summed to construct $M$.

**Note added.**—During completion of this work we became aware of a complementary study, to appear in the same arXiv posting, where a similar measurement scheme is presented [43]. The protocol introduced in that work follows the same steps as ours, where the state is first entangled with ancillas, before measurements in the computational basis are made, data from which are post-processed classically to infer properties of the state. In contrast to our proposal, no assumption is made about the formation of a quantum state design; instead the inverse map $M^{-1}$ needs to be explicitly computed.

**Acknowledgements.**—MM thanks Shivaji Sondhi for helpful discussions. We are especially grateful to Sounak Biswas for help and insight throughout this study. We

PROOFS OF QUANTUM STATE DESIGNS IN THE TOMOGRAPHIC ENSEMBLE

As mentioned in the main text, the construction of the tomographic ensemble [Eq. (1)] resembles that of the projected ensemble for a many-body state \( |\Psi^{SA}\rangle = U |0\rangle \) using the same unitary \( U \), as can be seen in Fig. S1. Comparing the two cases, we see that in the region \( A \), all qubits begin in the same initial state and are measured at the end of the process. The two protocols therefore differ only in the inputs and outputs of \( U \) in the region \( S \). (One could in principle also consider scenarios where measurement events occur throughout the dynamics, as in the study of ‘retrodiction’ in noisy quantum dynamics [44]; however we leave this possibility for future work.)

In this section, we make use of this resemblance to establish the existence of (approximate) quantum state designs in the tomographic ensemble, based on arguments that prove the same for the projected ensemble. We consider two cases: 1) where \( U \) is a single unitary drawn at random from the Haar ensemble over \( U(2^N) \), and 2) where \( U \) is a dual-unitary circuit containing \( t \geq N_S \) timesteps.

Haar-random unitary

The statement we wish to prove is as follows

**Theorem 1** For a unitary \( U \) chosen at random from the Haar ensemble over \( U(2^N) \), the tomographic ensemble forms an \( \epsilon \)-approximate \( k \)-design with probability \( 1 - \delta \) if

\[
N_A = \Omega(k N_S + \log(1/\epsilon) + \log \log(1/\delta))
\]

where \( \Omega(\cdot) \) contains a constant multiplicative prefactor, as well as constant offset terms.

The above implies that approximate quantum state designs are realised with overwhelmingly high probability in the limit of large system sizes (tending to unity double-exponentially fast in \( N_A \)), provided the number of ancillas scales quickly enough with the size of the system (at least as fast as \( k N_S \)).

*Proof of Theorem 1.*—Our proof uses many of the same analytical tools as the proof of the analogous theorem for the projected ensemble given in Ref. [29]. First, one shows that the average of \( \mathcal{E}^{(k)} \) over all choices of \( U \) matches the moments of the Haar distribution. Then, concentration of measure results can be used to bound the fluctuations of \( \mathcal{E}^{(k)} \) away from its average. This can be used to upper bound the probability that the trace distance \( \|\mathcal{E}^{(k)} - \mathcal{E}^{(k)}_{\text{Haar}}\|_1 \) exceeds an allowed tolerance \( \epsilon \). The main difference between the two proofs will be the derivation of an upper bound of the variation of \( \mathcal{E}^{(k)} \) considered as a function of \( U \).

The calculation of the averaged moments \( \mathbb{E}_U \mathcal{E}^{(k)} \) can be achieved by first proving that the probabilities \( q_m = \text{Tr}[F_m]/d_S \) and normalized wavefunctions \( |\phi_m\rangle = (\mathbb{I}_S \otimes |0\rangle_A)U^\dagger |m\rangle / \sqrt{q_m} \) are independent random variables. To see this, note that the joint probability density for a pair \( (q_m, |\phi_m\rangle) \) satisfies \( d\mathbb{P}(q_m, |\phi_m\rangle) = d\mathbb{P}(q_m, U S |\phi_m\rangle) \) by virtue of the fact that for any \( U \) realizing a given pair \( (q_m, |\phi_m\rangle) \), there exists a unitary \( U(U_S^\dagger \otimes I_A) \) occurring with the same probability (thanks to the invariance of the Haar measure), which realizes the pair \( (q_m, U S |\phi_m\rangle) \). This implies that the conditional probability density \( d\mathbb{P}(|\phi_m\rangle |q_m) \) is invariant under unitary rotations \( U_S \), and hence must be equal to the Haar measure for any \( q_m \). One can therefore separate averages of \( q_m \) and \( |\phi_m\rangle \), and using the definition of the moments (2) we have

\[
\mathbb{E}_U \mathcal{E}^{(k)} = \mathbb{E}_U \sum_m q_m \langle |\phi_m\rangle \langle \phi_m| \rangle^{\otimes k} = \sum_m (\mathbb{E}_U q_m) \mathbb{E}_{|\Psi\rangle \sim \text{Haar}} \langle |\Psi\rangle \langle |\Psi| \rangle^{\otimes k} = \mathcal{E}^{(k)}_{\text{Haar}}.
\]
We now seek to upper bound the probability of finding the \( k \)th moment a distance at least \( \epsilon \) away from its mean. This can be done using concentration of measure results, which describe the general phenomenon where probability distributions over high-dimensional manifolds become approximately uniform (see, e.g. Ref. [45]). Whereas the relevant quantity in Ref. [29] was a functional of a Haar-random state, here the moments of the tomographic ensemble are functionals of a Haar-random unitary. The particular lemma that we will need is therefore slightly different; it is stated as Lemma 3.2 in Ref. [46]:

**Lemma 1 (Lévy’s lemma)** Given a function \( f(U) \) that for any two \( U_{1,2} \in U(d) \) satisfies

\[
\frac{|f(U_1) - f(U_2)|}{\|U_1 - U_2\|_2} \leq \eta, \tag{S3}
\]

where \( \|C\|_2 := \sqrt{\text{Tr}[C^*C]} \) is the Frobenius norm, the probability that \( f \) deviates from its mean \( \mathbb{E}_U f \) by at least \( \epsilon \) can be upper bounded as

\[
\mathbb{P}(|f - \mathbb{E}f| \geq \epsilon) \leq 4 \exp\left(- \frac{2\epsilon^2}{9\pi^2\eta^2}\right). \tag{S4}
\]

The constant \( \eta \) appearing in Eq. (S3) is referred to as the Lipschitz constant of \( f \).

We will apply Lemma 1 to the scalar functional

\[
f_{ij}(U) := \langle i| \mathcal{E}^{(k)}[U]|j\rangle = \prod_{m=1}^k \frac{\langle i^{(m)}| F_m |j^{(m)} \rangle}{\text{Tr}|F_m|^{k-1}} \tag{S5}
\]

where \( |i\rangle = |i^{(1)}\rangle \otimes \cdots \otimes |i^{(k)}\rangle \) is a state in the \( k \)-fold replicated space, and each \( i^{(m)} \) runs over a basis for the Hilbert space of \( S \). First we need to compute the Lipschitz constant of \( f_{ij} \). This will proceed somewhat differently to the arguments of Ref. [29].

To bound the left hand side of (S3), we define a parametrization of matrices \( U(t) = (1 - t)U_1 + tU_2 \), which lies within the convex hull of unitary matrices for \( t \in [0,1] \). We then have

\[
\frac{|f(U_1) - f(U_2)|}{\|U_1 - U_2\|_2} = \left| \int_0^1 dt \left[ \frac{df(U(t))}{dt} \right] \right| = \left| \int_0^1 dt \text{Tr} \left[ \frac{\partial f}{\partial U} \frac{dU}{dt} \right] \right| \leq 2 \max_U \left\| \frac{\partial f}{\partial U} \right\|_2 \tag{S6}
\]

where \( \frac{dU}{dt} \), and the maximum is taken over all \( U \) in the convex hull of \( U(d) \). In the last step, we have used the Cauchy-Schwartz inequality applied to the Hilbert-Schmidt norm \( |\text{Tr}[AB]| \leq |A||B|_2 \), along with the constancy of \( \frac{\partial f}{\partial U} \) and the relation \( \|\frac{\partial f}{\partial U}\|_2 = \|\frac{\partial f}{\partial U'}\|_2 \). Note that our definition of the matrix derivative is \( \frac{\partial f}{\partial U}_{ab} = \frac{\partial f}{\partial U_{ba}} \) and \( \frac{\partial f}{\partial U_{ab}} = \frac{\partial f}{\partial U_{ba}} \), where the variables \( U_{ab} \) and \( U_{ba} \) are treated as being independent.

Using the expression \( F_m = (0_A|U|m) \langle m|U|0_A \rangle \) [Eq. (1)], the norm of the matrix derivative can be evaluated

\[
\left\| \frac{\partial f_{ij}}{\partial U} \right\|_2 = \|X + Y\|_2 \leq \|X\|_2 + \|Y\|_2 \tag{S7}
\]
where we have defined
\begin{align}
X &= \sum_{m} \sum_{l=1}^{k} \frac{\prod_{l' \neq l} (i(l') \mid F_m \mid j(l'))}{\text{Tr}[F_m]} (i(l) \otimes 0_A \mid U_{l} \mid m) (j(l) \otimes 0_A) \langle m | \\
Y &= (k - 1) \sum_{m} \frac{\prod_{l=1}^{k} (i(l') \mid F_m \mid j(l'))}{\text{Tr}[F_m]} (0_A \otimes \mathbb{I}_S) U_{l} \mid m \rangle \langle m | 
\end{align}

Now recalling the definition \( \tilde{F}_m = F_m / \text{Tr}[F_m] \), we can express the squared norms \( \|X\|_2^2 = \text{Tr}[X ^\dagger X] \) in terms of matrix elements of POVM operators
\begin{align}
\|X\|_2^2 &= \sum_{m} \sum_{l=1}^{k} \sum_{p=1}^{k} \delta_{j(l')}(p) \frac{\prod_{l' \neq l} (i(l') \mid \tilde{F}_m \mid j(l'))}{\prod_{l' \neq p} (j(l') \mid \tilde{F}_m \mid i(l'))} \text{Tr}[F_m] \langle i(l') \mid \tilde{F}_m \rangle \langle i(l') | \\
&= d_S \sum_{m} \sum_{l=1}^{k} \sum_{p=1}^{k} \delta_{j(l')(l')} (i_l \otimes i_p \otimes i(l)) | E_{l} (2k-1) | i_l \otimes i_p \otimes i(p) 
\end{align}

where \( | E_l \) is a tensor product of all \( | i(l') \rangle \) for \( l' \neq l \). Here we have invoked the representation of \( \mathcal{E}^{(2k-1)} \) in terms of the POVM operators; see the right hand side of Eq. (2). It is important to remember that \( U \) here can be any matrix in the convex hull of \( U(d) \), i.e. \( U = \sum_{i} \lambda_i V_i \) with \( \lambda_i \geq 0 \), \( \sum V_i ^\dagger V_i = \mathbb{I} \), and \( \sum \lambda_i = 1 \). This set is equal to the space of \( d \times d \) complex matrices satisfying \( \|U\|_{\infty} \leq 1 \). We can still use the form \( \mathcal{E}^{(2k-1)} = \sum_{m} q_m (| \phi_m \rangle \otimes \mathbb{I}) \), where \( | \phi_m \rangle \) are normalized wavefunctions, and \( q_m = \langle m | U (\mathbb{I}_S \otimes | 0_A \rangle \langle 0_A | U_{l} \mid m \rangle | / d_S \). We will make use of the following matrix inequality
\begin{align}
\mathcal{E}^{(1)} \equiv \frac{1}{d_S} \sum_{m} \langle 0_A | U_{l} \mid m \rangle \langle m | U_{l} \rangle | \leq \Pi / d_S 
\end{align}

which follows straightforwardly from the fact that \( \langle \phi | \mathcal{E}^{(1)} \rangle \phi = (\phi \otimes 0_A | U_{l} \rangle \langle 0_A | U_{l} \rangle \leq \langle \phi | \phi \rangle U_{l} ^\dagger U_{l} / d_S \). This implies that the summand of (S11) has modulus at most 1, and so summing over \( l \) we finally obtain \( \|X\|_2^2 \leq k^2 \).

Similarly, we can express \( \|Y\|_2^2 \) in terms of the moments \( \mathcal{E}^{(2k)} \):
\begin{align}
\|Y\|_2^2 &= (k - 1)^2 \sum_{m} \left| \prod_{l=1}^{k} (i(l) \mid \tilde{F}_m \rangle \langle j(l') | \right|^2 \text{Tr}[F_m] \\
&= (k - 1)^2 \langle i \otimes j | \mathcal{E}^{(2k)} | i \otimes j \rangle 
\end{align}

Following a similar line of reasoning as before, we have \( \langle i \otimes j | \mathcal{E}^{(2k)} | i \otimes j \rangle \leq 1 \). Hence \( \|Y\|_2^2 \leq (k - 1)^2 \). Putting everything together, we get
\begin{align}
\frac{|f_{ij}(U_1) - f_{ij}(U_2)|}{\|U_{1} - U_{2}\|_2} \leq \eta \leq 2k - 1 
\end{align}

The rest of the proof follows the same logic as Ref. [29]. Defining \( \Delta^{(k)} := \mathcal{E}^{(k)} - \mathcal{E}^{(k)}_{\text{Haar}} \), we have \( \|\Delta^{(k)}\|_1 \leq \sum_{i,j} |\Delta_{ij}^{(k)}| \). Therefore the probability that the trace distance exceeds some value \( \epsilon \) can be upper bounded
\begin{align}
P_{U \sim \text{Haar}} \left( \|\mathcal{E}^{(k)}[U] - \mathcal{E}^{(k)}_{\text{Haar}}\|_1 \geq \epsilon \right) \leq P_{U \sim \text{Haar}} \left( \sum_{i,j} |\Delta_{ij}^{(k)}| \geq \epsilon \right) \leq P_{U \sim \text{Haar}} \left( |\Delta_{ij}^{(k)}| \geq \epsilon / d_S^k \right) \text{ for some } i,j 
\end{align}
Employing Lemma 1 and taking a union bound, we have
\[
\mathbb{P}_{U \sim \text{Haar}} \left( \| \mathcal{E}^{(k)}[U] - \mathcal{E}^{(k)}_{\text{Haar}} \|_1 \geq \epsilon \right) \leq 4d_S^2 k \exp \left( -\frac{d c^2}{18 \pi^3 (2k - 1) d_S^4} \right) \tag{S16}
\]
For qubits we have \( d = 2^{N_S + N_A} \) and \( d_S = 2^{N_S} \), and so the tomographic ensemble forms an \( \epsilon \)-approximate \( k \)-design with probability \( 1 - \delta \) whenever \( \delta \) is less than the right hand side of the above, giving
\[
2^{N_A} \geq \frac{18 \pi^3 (2k - 1)^2 4^{NK_S - 1}}{\epsilon^2} \left( 2kN_S \log 2 + \log(4/\delta) \right) \tag{S17}
\]
This is achieved whenever \( N_A \) scales according to the relation quoted in Eq. (S1).

\[ \square \]

**Dual-unitary circuit**

The second case where the existence of \( k \)-designs can be rigorously proven is when the unitary \( U \) is a brickwork circuit made up of two-site gates that are each dual-unitary. In this section, we will allow for arbitrary local Hilbert space dimension \( q \geq 2 \), i.e. we consider systems of \( N \) qudits; accordingly, measurement outcomes \( m \) can take \( q \) distinct values.

A unitary gate acting on two qudits can be viewed as a rank-4 tensor \( U_{i_1i_2}^{o_1o_2} \), with two indices \( i_{1,2} \) for the initial state of the qudits and two indices \( o_1,2 \) for the corresponding outputs. The gate is dual-unitary if the components of this tensor also describe a unitary matrix when viewed as a map from inputs \( i_1, o_1 \) to outputs \( i_2, o_2 \). This is illustrated in Fig. S2(a). The space of dual-unitary gates acting on qubits (\( q = 2 \)) was classified in Ref. [47]. Brickwork circuits made up of dual-unitary gates describe form of many-body quantum dynamics wherein many properties can be calculated exactly, such as two-point correlation functions, entanglement entropies, and out-of-time-order correlators [48–50].

Recently it has been shown that under certain conditions, a many-body wavefunction \(| \Psi^{SA} \rangle = U |0 \rangle \) generated by time evolution under a dual-unitary circuit \( U \) realises an exact \( k \)-design in its projected ensemble, in the limit of an infinite number of ancilla qudits \( N_A \rightarrow \infty \) [31–33]. In order for this result to hold, the dual-unitary must not be fine-tuned to an integrable point, and the initial state \(|0 \rangle \) and measurement basis \(|m \rangle \) must form a solvable measurement scheme (using the terminology of [32]), meaning that certain criteria that depend on the circuit in question must be met. We will leverage results that were proved in this context to show that the tomographic ensemble formed from such a unitary will also form exact \( k \) designs in the limit \( N_A \rightarrow \infty \).

By analogy to the moments of the projected ensemble [32], here the moments of the tomographic ensemble can be studied analytically using a replica trick. We generalise the definition of the ensemble moments (2) to
\[
\mathcal{E}^{(n,k)} = \sum_m q_m^{n+k} \left( \langle \phi_m | \phi_m \rangle \right)^{\otimes k} = \sum_m (\text{Tr}[F_m])^n F_m^{\otimes k} \tag{S18}
\]
where \( F_m \) are the unnormalized POVM operators defined in Eq. (1). This representation can be generalized to any number of layers \( t \) (\( t = 4 \) layers are shown above). The properly normalized \( k \)th moment is recovered by analytically continuing \( n \) and taking the replica limit \( n \to 1 - k \).

Each term in the sum in (S18) can be expressed in terms of an \( l \)-fold copy of the original circuit \( U := (U \otimes U^*)^\otimes l \), where \( l = n + k \). In all copies, the initial state of the ancillas are the same state \(|0_A\rangle\), and the final states of all qudits are projected onto \(|m\rangle\langle m|\). For \( n \) of the copies, the inputs to the unitary in the region \( S \) are traced out, while for the remaining \( k \) copies, those inputs are left as free, constituting the components of the summand in (S18). We will focus on initial states and measurement bases that are product states here. The summand can be graphically represented using the notation described in Fig. S2 as

\[
(\text{Tr}[F_m])^n F_m^{\otimes k} \quad \text{(S19)}
\]

We have highlighted the region corresponding to qudits in \( S \) to distinguish this part of the circuit from the part acting on ancilla qudits. The latter part of the diagram will simplify upon taking the limit \( N_A \to \infty \).

Given that the initial state and measurement basis are product states, we will need to assume an additional property of \( U \) which ensures that the measurement scheme is solvable. This property is found in the kicked Ising model [47], as well as a family of gates introduced in Ref. [32]; we refer interested readers to that work for details. Here, we will simply state this property, and assume it in the following. For any computational basis states \( m_1, m_2 \), the two-site gates we consider here must satisfy

\[
\begin{pmatrix}
m_1 \\
m_2
\end{pmatrix} = \begin{pmatrix} a & d \\ d & a \end{pmatrix}
\quad \text{(S20)}
\]

When this property is obeyed, the part of the circuit (S19) that acts on ancilla qudits simplified considerably in the limit \( N_A \to \infty \) [32]

\[
q^{2(l-1)N_A} \times \sum_{m_1, \ldots, m_{NA}} \ldots \prod_{l \text{ layers}} \text{const.} \sum_{m_1} \sum_{\sigma \in \Sigma_l} \pi_{\sigma} \quad \text{(S21)}
\]

where the components of the rank-1 tensors \( \pi_{\sigma} \), defined for each element of the permutation group of \( l \) objects \( \sigma \in \Sigma_l \), are given in Fig. S2(g). The above holds for any integer \( k \) and any even number of layers \( t \geq 2 \), provided that the circuit is not integrable. An analogous result for odd \( t \) can also be obtained, with different boundary conditions at the top. The factor of \( q^{2(l-1)N_A} \) is required to ensure that the left hand side is finite and bounded in the limit \( N_A \to \infty \).

Generalized moments (S18) of the projected ensemble of the wavefunction \(|\Psi^{SA}\rangle = U |0\rangle\) can be computed with the help of Eq. (S21). By analytically continuing to \( n \to 1 - k \), the properly normalized moments can be obtained.
When the number of layers $t$ is at least as large as $N_S$, one finds that the projected ensemble forms an exact $k$-design \cite{31–33}. We will use similar arguments to show that the tomographic ensemble also forms a $k$-design for $t \geq N_S$. A key ingredient will be the following relations

$$
\begin{align*}
\pi & = \text{unitary} \\
\pi & = \text{dual unitary}
\end{align*}
$$

for any permutation $\sigma$. These follow from the unitarity and dual-unitarity of the two-qudit gates. In addition, the solvable measurement scheme condition (S20) can be rewritten in the replicated space as

$$
\sum m_1 m_2 m_3 \pi_\sigma = \sum m_1 \sum \sigma \in \Sigma_k \pi_\sigma \tag{S23}
$$

which will be made use of in the following.

The generalized moment is obtained by summing Eq. (S19) over $m$ and applying (S21), which leads to a significant simplification, and subsequent application of Eqs. (S22, S23) allows further reduction (a representative case $t = 4$, $N_S = 2$ is shown in the following diagrams, but the arguments steps are readily generalised)

$$
\mathcal{E}^{(n,k)} \propto \sum m_1 m_2 m_3 \sum \sigma \in \Sigma_k \pi_\sigma \tag{S24}
$$

Finally, by performing the trace over the $n$ copies [see Fig. S2(f)], we find that the generalized moment is an equal-weight sum of all permutation tensors over $k$ elements $\mathcal{E}^{(n,k)} \propto \sum \sigma \in \Sigma_k \pi_\sigma$. The dependence on $n$ is then entirely through a constant of proportionality, and so the analytic continuation $n \rightarrow 1 - k$ is readily taken. In fact, the value of this proportionality constant in the replica limit is fixed by the condition that $\text{Tr}[\mathcal{E}^{(k)}] = 1$. Putting everything together, and noting that the sum over all permutation operators in the $k$-fold replica space is precisely the $k$th moment of the Haar ensemble, we conclude that the tomographic ensemble forms an exact $k$-design for all $k$. \hfill \square

\section*{INCLUDING RANDOMNESS}

In the main text, we described a ‘semi-randomized’ version of our original protocol, where in each repetition of the experiment, $U$ is chosen at random from some distribution of unitaries that are all native to the quantum device in question. Here we describe how this modification reduces the systematic error of the estimators, and reduces the overheads in terms of number of ancillas.

In this section, we will make reference to a scenario where the unitary is sampled from a discrete probability distribution $\{(p_c, U_c)\}$, where $c = 1, \ldots, C$ labels distinct unitaries $U_c$, which occur with probability $p_c$ (note however that all results can be straightforwardly generalized to continuous probability distributions). When the unitary $U$ itself is decided by a random process, we can write down a POVM $\{F_{m,c}\}$ such that the probability of both choosing a specific unitary $U_c$, and obtaining the outcome $m$ is $\text{Tr}[\rho_S F_{m,c}]$. Specifically, we have

$$
F_{m,c} = p_c \times F_{m|U_c} \tag{S25}
$$

where $F_{m|U_c}$ is the POVM operator (1) with $U$ replaced by $U_c$. Since each $\{F_{m|U_c}\}_m$ is itself a POVM, we have $\sum_{m,c} F_{m,c} = I$ as desired. Note that this formalism could be used to capture classical shadow tomography, where...
case, we keep the probabilities uniform $H_k$ for our protocol. Governing the systematic error of the estimators, we see that adding randomness allows one to reduce any such error in the discrepancy between the $k$-value of the trace distance $\sum_h |E_h|^2 = 2$ trace distance for a particular family of different distributions of unitaries $U_c$. Now, we observe that the $k$-moments of the full POVM $F_{m,c}$ [Eq. (2)] are convex combinations of the moments for each individual POVM $F_{m|U_c}$, namely

$$E^{(k)}_{\text{full}} \equiv \sum_{c=1}^{C} \sum_m \text{Tr}[F_{m,c}](F_{m,c})^\otimes k = \sum_{c=1}^{C} p_c E^{(k)}[F_{m|U_c}]$$

(S26)

where $E^{(k)}[F_{m|U_c}]$ is the $k$th moments of the tomographic ensemble for the POVM (1) where the unitary $U_c$ is used. If each separate POVM $\{F_{m|U_c}\}_m$ deviates from a perfect 2-design by an amount $\Delta_c$ (as quantified by the trace distance $1/2 \|E^{(2)} - E^{(2)}_{\text{Haar}}\|_1$), then by the triangle inequality $E^{(2)}_{\text{full}}$ will deviate from a state design by at most the average value of the trace distance $\sum_c p_c \Delta_c$. Roughly speaking, if the projectors that make up each $F_{m|U_c}$ are uncorrelated with one another, then we expect that the differences $E^{(2)}[F_{m|U_c}] - E^{(2)}_{\text{Haar}}$ will typically be in different directions in operator space, and so the errors will compound sub-additively, yielding a smaller value of the trace distance. Since the discrepancy between the $k = 2$ moments of the tomographic ensemble and the corresponding Haar moments governs the systematic error of the estimators, we see that adding randomness allows one to reduce any such error in our protocol.

To verify that the moments of the full ensemble $E^{(k)}_{\text{full}}$ are indeed closer to being a $k$-design than each separate POVM, we compute the $k = 2$ trace distance for a particular family of different distributions of unitaries $\{p_c, U_c\}$. In each case, we keep the probabilities uniform $p_c = 1/C$, and vary the number of different unitaries $C$. Each $U_c$ is generated by the tilted-field Ising Hamiltonian discussed in the main text, $H(t) = \sum_j X_j X_{j+1} + h^x(t) X_j + h^y(t) Y_j$. The values of $h^x,y(t)$ change abruptly every $\tau = 0.5$ time units, and each unitary $U_c$ has a different sequence of field values. Before running any simulations, we choose the actual field values for each $c$ through independent random sampling from a normal distribution with zero mean and standard deviation $\sqrt{2}$, and use these field values to construct the moments (S26). In the limit $C \to \infty$, this describes the protocol used to generate the data shown in Fig. 3. We see that increasing $C$ does indeed reduce the trace distance, and empirically we find that the plateau value of $\Delta^{(2)}$ scales as $1/\sqrt{C}$. Notably, this is the behaviour that we would expect if we assumed that every wavefunction $|\phi_{m,c}\rangle$ in the ensemble was an independent randomly distributed vector. Of course, in the true $C \to \infty$ limit, one can find two possible unitaries $U_c, U_c'$ that are very close to one another such that this assumption of independence will fail; thus at large enough $C$ the trace distance should saturate to a finite (but very small) value. Since constructing the tomographic ensemble for large values of $C$ is computationally demanding, we find it easier to properly assess the performance of this randomized protocol by simulating the whole procedure, as in the data presented in Fig. 3.

FIG. S3. Trace distance $\Delta^{(2)}$ of the tomographic ensemble where the unitary is chosen at random from a discrete probability distribution $\{(p_c, U_c)\}$, where $c = 1, \ldots, C$, and the moments formed as in Eq. (S26). We vary the number of different unitaries $C$, from the smallest value $C = 1$ (green), doubling each time to $C = 2, 4, 8, \ldots$, up to $C = 128$ (purple). We always choose a uniform distribution for $p_c = 1/C$, and each unitary $U_c$ is generated by the tilted-field Ising Hamiltonian, as discussed in the main text. Increasing $C$ leads to better convergence towards a $k$-design—in particular, after a $C$-independent time, $\Delta^{(2)}$ saturates at a value proportional to $C^{-1/2}$.

$U_c$ is sampled from the appropriate distribution of unitaries (global Clifford circuits or local Pauli rotations). The difference here is that a state design is approximately formed for each $U_c$, whereas in shadow tomography the POVM for a single unitary is far from being a $k$-design for $k \geq 2$, since the number of different possible measurement outcomes is not big enough ($2^{N_c}$ compared to the minimum number $4^N$ required to form a 2-design).

Now, we observe that the $k$th moments of the full POVM $F_{m,c}$ [Eq. (2)] are convex combinations of the moments for each individual POVM $F_{m|U_c}$, namely
Note that adding randomness does not increase the classical computational overhead because the inverse map $\mathcal{M}^{-1}$ is chosen to be the universal form (5). If, on the other hand, we were to compute $\mathcal{M}^{-1}$ exactly, we would have to compute $2^N \times C$ individual wavefunctions, where $C$ is the number of different unitaries in the distribution. Also, from our simulations we find that the full ensemble can approach a 2-design very closely even with a modest number of ancillas, because trace distance for each separate POVM $\{F_{m[U]}\}_m$ does not need to be particular small, provided that we can sample from a sufficiently diverse range of unitaries.

ACCOUNTING FOR SYMMETRIES

Some quantum simulators possess intrinsic symmetries that cannot be readily broken, e.g. number conservation in ultracold atomic gases. This restricts the space of unitaries $U$ that are available, which in turn leads to constraints on the POVMs that can be realised with our protocol. Focusing on Abelian symmetry groups, in this section we will show that the moments of the tomographic ensemble tend towards different universal form that respects this symmetry. Specifically, within each symmetry charge sector an approximate state design is formed. Again this occurs provided that $U$ is sufficiently entangling, and, in the case where the symmetry is continuous, the initial state of the ancillas must also have a small enough effective chemical potential (i.e. $|0\rangle_A$ is not close to being a maximum- or minimum-charge state).

The Hilbert space of a system that respects some Abelian symmetry can be decomposed into charge sectors $q$, spanned by orthogonal projectors $P_q$, which are not coupled by symmetric unitaries: $P_q U P_{q'} = 0$ for $q \neq q'$. Any target density matrix $\rho_S$ that can be prepared using symmetric operators will also be constrained to have vanishing coherences between different charge sectors, i.e. $[\rho_S, P_q] = 0$. (In the nomenclature of Ref. [51], this corresponds to a ‘weak symmetry’, in contrast to a state that has support in only one charge sector, which is ‘strongly symmetric’.) Therefore, only charge-diagonal observables and states need be considered, since operators that couple different charge sectors have vanishing expectation values. Symbolically, we have

$$O = \bigoplus_q O_q, \quad \rho_S = \bigoplus_q \rho_q.$$  \hspace{1cm} (S27)

We naturally presume that computational basis states and the ancilla initial states each have definite charge. Therefore each POVM operator $F_m$ [Eq. (1)] will lie in a particular charge sector $q(m)$, where $q(m)$ is the charge of the system that is required to match the total system plus ancilla charge before applying $U$ to the final measured charge $m$. This constraint prevents the formation of full state designs, since superpositions of states with different charges are forbidden. Instead, we find that generic symmetry-respecting dynamics yields a POVM for which the tomographic ensemble forms an approximate state design within each charge sector—we call such a distribution a ‘block-diagonal state design’. That is, we can decompose $\mathcal{E}^{(k)} = \bigoplus_q \mathcal{E}_q^{(k)}$, where $\mathcal{E}_q^{(k)}$ contains only terms in Eq. (2) for which $q(m) = q$, and we find that $\mathcal{E}_q^{(k)}$ approaches the $k$th moment of the Haar ensemble over span($P_q$). Note that the block-diagonal Haar ensemble is the distribution that maximizes randomness subject to the constraints imposed by symmetry.

Provided that $\mathcal{E}^{(2)}$ takes this universal form, expectation values of charge-diagonal operators can be estimated using (4), after replacing the expression in Eq. (5) with a block-diagonal superoperator

$$\mathcal{M}^{-1} = \bigoplus_q \mathcal{M}^{-1}_q$$

where $\mathcal{M}^{-1}_q[O_q] = (d_q + 1)O_q - \text{Tr}[O_q]P_q.$ \hspace{1cm} (S28)

where $O_q$ is the submatrix of the operator $O$ contained within the charge sector $q$, as in Eq. (S27).

It is relatively straightforward to see that if the moments of the tomographic ensemble do converge to a universal form, then it must be the block-diagonal state design described above. This follows from considering the behaviour of a unitary $U$ sampled from the maximally random distribution of charge-conserving unitaries, where each submatrix $U_q$ describing the behaviour of $U$ within charge sector $q$ is drawn from the Haar ensemble. By considering one block $q$ at a time, one can use the same method as in Eq. (S2) to see that the mean value of $\mathcal{E}_q^{(k)}$ is equal to the $k$th moments of the Haar ensemble over the space spanned by $P_q$. The concentration of measure results given in the previous section can also be used to bound the deviation of a given symmetry sector from being a state design, with the Hilbert space dimensions $d, d_S$ replaced with their appropriate charge-restricted values: Specifically, $d_S$ should be replaced with the number of system states with a fixed charge $q$, and $d$ should be replaced with the number of measurement outcomes.

$$\text{tr}\left(\mathcal{E}_q^{(k)} P_q\right) = \langle \mathcal{E}^{(k)} \rangle_q,$$  \hspace{1cm} (S29)

where $\langle \mathcal{E}^{(k)} \rangle_q$ is the $k$th moment of the Haar ensemble over span($P_q$), and $\mathcal{E}_q^{(k)}$ is a block-diagonal superoperator in the basis of $P_q$. This expression shows that the moments of the state design are equal to the moments of the Haar ensemble, up to a small error that depends on the number of ancillas used. If we assume that the moments of the Haar ensemble are close to the universal form (5), then we can use this result to estimate the accuracy of our simulation.

$$\text{tr}\left(\mathcal{E}_q^{(k)} P_q\right) = \langle \mathcal{E}^{(k)} \rangle_q$$

where $\langle \mathcal{E}^{(k)} \rangle_q$ is the $k$th moment of the Haar ensemble over span($P_q$), and $\mathcal{E}_q^{(k)}$ is a block-diagonal superoperator in the basis of $P_q$. This expression shows that the moments of the state design are equal to the moments of the Haar ensemble, up to a small error that depends on the number of ancillas used. If we assume that the moments of the Haar ensemble are close to the universal form (5), then we can use this result to estimate the accuracy of our simulation.

$$\text{tr}\left(\mathcal{E}_q^{(k)} P_q\right) = \langle \mathcal{E}^{(k)} \rangle_q$$

where $\langle \mathcal{E}^{(k)} \rangle_q$ is the $k$th moment of the Haar ensemble over span($P_q$), and $\mathcal{E}_q^{(k)}$ is a block-diagonal superoperator in the basis of $P_q$. This expression shows that the moments of the state design are equal to the moments of the Haar ensemble, up to a small error that depends on the number of ancillas used. If we assume that the moments of the Haar ensemble are close to the universal form (5), then we can use this result to estimate the accuracy of our simulation.
that could arise starting from a state where the system qubits have charge $q$, and the ancilla qubits have the charge determined by $|0\rangle_A$.

For discrete symmetry groups, $d$ increases exponentially with system size for each charge block as before, and so state designs are formed with overwhelmingly high probability. However, if the symmetry is continuous (such that there is a conserved charge density), then the effective dimension $d$ will scale much more slowly with system size when the charge of the ancilla initial state has near-maximum or near-minimum charge, reflecting the fact that there are fewer possible final measurement outcomes $m$, that are compatible with the initial charge configuration. Because of this, the ancilla initial state should be initialized with a non-extremal charge distribution if one is to expect formation of block-diagonal quantum state designs.

We also provide numerical evidence that for representative symmetry-conserving unitaries, the tomographic ensemble approaches a block-diagonal state design. As a representative example, we consider dynamics generated by the XXZ Hamiltonian in a staggered longitudinal field

$$H = \sum_j X_j X_{j+1} + Y_j Y_{j+1} + \Delta Z_j Z_{j+1} + (-1)^j h^z Z_j$$

(S29)

This model possesses a $U(1)$ symmetry generated by operators $e^{i\theta \sum_j Z_j/2}$, which implements a rotation of all spins by an angle $\theta$ about the $z$-axis. The staggered field is included to break the integrability of this model, which allows for chaotic dynamics. Again we use Floquet evolution $U = U_F$, with $U_F = e^{-iH_2\tau}e^{-iH_1\tau}$, where $H_{1,2}$ have different values of the anisotropy parameter $\Delta$. In our simulations, we pick $\tau = 0.5$, and $h^z = 0.6$, $\Delta = 0.8$ in $H_1$, and $\Delta = -1.7$ in $H_2$. We have verified that qualitatively similar behaviour is seen for other choices of parameters.

The initial state of the ancillas is chosen to be a staggered state $\bigotimes_j [|0\rangle_{2j-1} \otimes |1\rangle_{2j}]$. This state is chosen because there are a large number of states with the same total charge as this, compared to states that have near-extremal magnetization, i.e. those that are close to all $|0\rangle$, or all $|1\rangle$. This ensures that there will be a large number of different possible measurement outcomes, which is necessary for the formation of a state design. We have found that a much larger number of ancillas are needed to form an approximate state design when the initial state has maximum magnetization.

We compute the trace distance $\Delta^{(2)}$ between the $k = 2$ moments of the tomographic ensemble and the corresponding moments of the block-diagonal Haar ensemble. The results are plotted in Fig. S4. Again we see similar trends to the trace distance for the tilted-field Ising model: After an initial transient period, the trace distance plateaus at a value that scales exponentially with the number of ancillas. This behaviour can be understood in the same way as before, by noting that the trace distance is a sum of contributions from each charge sector $q$, and that the number of measurement outcomes $m$ that reside in each sector is exponentially small in $N_A$ for all $q$ (assuming $N_A/N_S$ is large).

In addition to conservation laws that are associated with unitary symmetries, one could in principle also consider conservation of energy due to time-translation symmetry. This applies when $U$ is generated from evolution under a...
time-independent Hamiltonian $U = e^{-iHt}$. However, from the results of Ref. [29], where the projective ensemble is studied, we anticipate that the evolution time required to reach the appropriate universal form will be much longer in this case. Since it is almost always possible to introduce some form of time-dependence in the Hamiltonian in experiments, we will not address this case here, instead leaving it to future work.

DETAILS OF CLASSICAL POST-PROCESSING

In this section we provide additional details on how properties of the target state $\rho_S$ can be estimated from experimentally observed measurement outcomes.

Optimality of the inverse map (4)

In the main text, we stated that the choice of inverse map $G$ that minimizes the variance (averaged over all initial input states) is given by Eq. (4). Here we prove this statement. Our logic follows a similar line of reasoning to the arguments given in Ref. [40], with the difference that here—in the spirit of shadow tomography [21–23]—the goal is to estimate specific expectation values, rather than perform full tomography of the density matrix.

For a given informationally complete POVM channel $\mathcal{F}$ [Eq. (3)], a linear estimator $\hat{\theta}_O$ for any expectation value $\langle \mathcal{O} \rangle$ can be represented as a dual vector $\langle w \rangle \in \mathbb{R}^{2^N}$ satisfying $\langle w | \mathcal{F} \rangle = \langle \mathcal{O} \rangle$ (see the main text). Thanks to this latter condition, the choice $\hat{\theta}_O = M^{-1} \sum_w^{M} \langle w | m^{(r)} \rangle$ (where $m^{(r)}$ is the measurement bitstring for repetition $r$) results in an unbiased estimator, since $E[\langle w | m^{(r)} \rangle] = \langle w | \mathcal{F} \rangle_{\rho_S} = \langle \mathcal{O} | \rho_S \rangle = \langle \mathcal{O} \rangle$. While performance could in principle be improved by harnessing more sophisticated nonlinear estimation schemes, e.g. maximum likelihood estimation, here we mainly analyse linear estimators. (One relatively simple example employed in Ref. [23] is to calculate a median-of-means, by harnessing more sophisticated nonlinear schemes, e.g. maximum likelihood estimation, here we mainly analyse linear estimators. (One relatively simple example employed in Ref. [23] is to calculate a median-of-means, rather than just the mean used here, which reduces the chances of finding outliers.)

Since $\langle w \rangle$ is non-unique whenever $N_A > N_S$, we wish to find a choice that is optimal. Specifically, our aim is to minimize the variance of the estimator, averaged over all possible input states $\rho_S$. As explained in the main text, this is equivalent to minimization of

$$\Delta[w] = \frac{1}{d_S} \sum_m w_m^2 \text{Tr}[F_m]$$

subject to the constraint $\langle w | \mathcal{F} \rangle = \langle \mathcal{O} \rangle$. We will show that the choice $\langle w_0 \rangle = \langle \mathcal{O} | G_0 \rangle$, where the inverse map $G_0$ is given in Eq. (4), achieves this minimum.

Firstly, we show that $\langle w_0 \rangle$ is a valid estimator. First observe that the channel $\mathcal{M}$ defined in Eq. (4) can be written as either $\mathcal{F}^{1|\mathcal{F}}$ or $\mathcal{F}^{1|\mathcal{F}}$. Then, we have

$$\langle w_0 | \mathcal{F} \rangle = \langle \mathcal{O} | \mathcal{M}^{-1} \mathcal{F}^{1|\mathcal{F}} = \langle \mathcal{O} | \mathcal{M}^{-1} \mathcal{M} = \langle \mathcal{O} \rangle$$

By virtue of the above, any valid estimator $\langle w \rangle$ can be written as $\langle w \rangle = \langle w_0 \rangle + \langle b \rangle$, where $\langle b \rangle$ satisfies $\langle b | \mathcal{F} \rangle = 0$. Now we evaluate

$$\Delta[w] = \Delta[w_0] + \Delta[b] + \frac{2}{d_S} \sum_m \text{Tr}[F_m] \langle w_0 | m \rangle \langle m | b \rangle$$

We now use the explicit form of $\langle w_0 \rangle$ given in (4) to obtain $\langle w_0 | m \rangle = \langle \mathcal{O} | \mathcal{M}^{-1} | F_m \rangle / \text{Tr}[F_m]$. The factors of $\text{Tr}[F_m]$ then cancel in the summand in (S32), allowing us to write

$$\sum_m \langle w_0 | m \rangle \langle b | m \rangle \text{Tr}[F_m] = \sum_m \langle \mathcal{O} | \mathcal{M}^{-1} | F_m \rangle \langle m | b \rangle = \sum_m \langle \mathcal{O} | \mathcal{M}^{-1} \mathcal{F}^{1|\mathcal{F}} | b \rangle$$

Now, since $\langle b | \mathcal{F} \rangle = 0$ by definition, the sum in (S33) vanishes. Since $\Delta[b] \geq 0$ for any $\langle b \rangle \in \mathbb{R}^{2^N}$ with equality if and only if $b = 0$, we conclude that $\langle w_0 \rangle$ achieves the global minimum of the functional $\Delta$, subject to the constraint of
being a valid estimator. The value of this global minimum is

$$\Delta[w_0] = \frac{1}{d_S} \langle O | \mathcal{M}^{-1} \left( \sum_m \text{Tr}[F_m] \hat{F}_m \right) \mathcal{M}^{-1} | O \rangle = \frac{1}{d_S} \langle O | \mathcal{M}^{-1} | O \rangle,$$

with a corresponding average variance of $\mathbb{E}_{\rho_S} \text{Var} \hat{\theta}_O|_{w_0} = M^{-1} (\Delta[w_0] - \mathbb{E}_{\rho_S} \langle O \rangle^2)$. □

Bounding the variance of estimators

As we showed in the previous section, the dual vector $(w_0|$ produces the estimator with the smallest possible variance averaged over all possible input states. However, this does not give us complete information about the variance that one would find for specific choices of $\rho_S$. Indeed, in principle there could exist particular adversarial input states for which the variance is exceptionally high, even if the average variance is small. To ascertain $\text{Var} \hat{\theta}_O$ for any particular $\rho_S$, we can use Eq. (6), which is expressed in terms of the third moments of the tomographic ensemble $\mathcal{E}^{(3)}$ [see Eq. (2)]. Here, we will use this expression to obtain upper bounds for the variance of estimators of expectation values, as well as nonlinear properties of $\rho_S$.

We are particularly interested in cases where the moments of the tomographic ensemble approach their universal maximum-randomness forms (the form in question depends on whether blocking is used or not, and whether any symmetries are present). In these cases, analytic expressions for $\mathcal{M}^{-1}$ and $\mathcal{E}^{(3)}$ can be obtained which allow the variance, treated as a joint functional of $\rho_S$ and $O$, to be specified explicitly. We aim to obtain simple upper bounds for the variance in such cases, focusing on setups with no conservation laws, either with or without blocking. As we will show, in the case with (without) blocking the functional form of the variance becomes the same as that of classical shadow tomography with random global (local) gates [23].

To prove this, it will be helpful to represent conventional shadow tomography using the POVM formalism employed in this work. There, a unitary $U$ is applied to the system only (no ancillas are used), before measurement in the computational basis, giving an outcome $m_S$. The unitaries are randomly sampled from an appropriate discrete set $U$ with probabilities $p_U$. We can then define POVM operators $F_{m_S,U}$ as

$$F_{m,S,U} = p_U U^\dagger |m_S\rangle \langle m_S| U$$

(S35)

Each operator of the above form corresponds to an event where the unitary chosen is $U$, and the subsequent measurement outcome is $m$. Again, these are rank-1 projectors, and so moments of the tomographic ensemble can be formed:

$$\mathcal{E}^{(k)} = \sum_{U \in \mathcal{U}} \sum_{m_S \in \{0,1\}^{N_S}} p_U \left( U^\dagger |m_S\rangle \langle m_S| U \right)^\otimes^k$$

(S36)

In addition to Eq. (6), we will also prove a useful result that allows us to express the variance of nonlinear estimators in terms of the third moment of the tomographic ensemble.

No blocking

In the protocol with a single collection of ancillas and no conservation laws, the tomographic ensemble approaches a $k$-design over all wavefunctions in the Hilbert space of $S$. The second and third moments therefore take their universal form

$$\mathcal{E}^{(2)} = \frac{1}{d_S(d_S + 1)} (\mathbb{I} + \pi_{(12)})$$

(S37)

$$\mathcal{E}^{(3)} = \frac{1}{d_S(d_S + 1)(d_S + 2)} \sum_{\sigma \in \Sigma} \pi_{\sigma}$$

(S38)

Because the POVM operators are rank-1 projectors $F_m = d_S q_m |\phi_m\rangle \langle \phi_m|$, the second moment $\mathcal{E}^{(2)}$ fully specifies the map $\mathcal{M}$. Specifically, the two share the same matrix elements

$$\langle ij | \mathcal{E}^{(2)} | kl \rangle = \frac{1}{d_S} \times \langle E_{ik} | \mathcal{M} | E_{jl} \rangle$$

(S39)
The corresponding channel $\mathcal{M}$ will have an analogous block structure $\mathcal{M} = \bigotimes_{j=1}^{n} (|\mathbb{I}\rangle\langle\mathbb{I}|/(d_j + 1))$, where $d_j$ is the Hilbert space dimension of block $j$.

Obtaining a state-independent bound on the variance [analogous to (S40)] is more complicated in this case. If each block is a single qubit, $d_j = 2$, the problem becomes equivalent to bounding the variance of classical shadow tomography with random local Pauli measurements. This is because the uniform distribution over Pauli rotations forms a 3-design for a single qubit. Hence, the moments $k \leq 3$ of the POVM for local shadow tomography [Eq. (S36)] are the same as those of the tomographic ensemble of our protocol for $k \leq 3$. The variance of the estimators $\hat{\theta}_O$ is fully determined by the third moments $\mathcal{E}^{(k \leq 3)}$, and so we can conclude that our scheme allows one to estimate expectation values to the same degree of uncertainty.

Useful upper bounds for the variance in conventional shadow tomography are given in the supplement of Ref. [23]. In particular, we have

$$\text{Var} \hat{\theta}_O \mid_{3\text{-design}} = \frac{1}{M} \frac{d_S}{d_S^2} + \frac{1}{2} \left( \text{Tr}[\mathcal{O}_0^2] + 2 \text{Tr}[\rho_S \mathcal{O}_0^2] \right) \leq \frac{1}{M} \times 3\|\mathcal{O}_0\|_2^2,$$

(S40)

where $\mathcal{O}_0 = \mathcal{O} - \text{Tr}[\mathcal{O}]/d_S$ is the traceless part of $\mathcal{O}$, and $\|C\|_2 = \sqrt{\text{Tr}[C^\dagger C]}$ is the Frobenius norm. Eq. (S40) tells us that expectation values of operators with bounded Frobenius norm can be estimated to a good accuracy using a reasonable number of repetitions, regardless of what the input state. Importantly, for many observables (such as fidelities $\mathcal{O} = |\Psi\rangle\langle\Psi|$) this upper bound does not scale with system size.

Measurement outcomes can be used to construct other properties of $\rho_S$ in addition to expectation values. Specifically, estimators for nonlinear functionals of $\rho_S$, such as Rényi entropies, can also be obtained, as detailed in the following section. We note that bounds on the variance of such estimators proved in Ref. [23] also carry through to our protocol.

**Blocking**

To avoid a classical computational cost that scales exponentially in the size of $S$, it may be necessary to divide the system into $n$ blocks and entangle each with a set of decoupled ancillas $A_j$, $j = 1, \ldots, n$. In this case, the POVM operators have a tensor product structure $F_{m_1, \ldots, m_n} = \bigotimes_{j=1}^{n} F_{m_j}^{(j)}$, which precludes the formation of a state design over the entire Hilbert space. Instead, for generic choice of $U_j$, a state design within each block will be formed, and so the $k$th moments will have the form

$$\mathcal{E}^{(k)} = \bigotimes_{j=1}^{n} \mathcal{E}_{\text{Haar}}^{(k)}.$$

(S41)

The corresponding channel $\mathcal{M}$ will have an analogous block structure $\mathcal{M} = \bigotimes_{j=1}^{n} (|\mathbb{I}\rangle\langle\mathbb{I}|/(d_j + 1))$, where $d_j$ is the Hilbert space dimension of block $j$.

In Ref. [23] it was shown that the variance can be upper bounded by $\text{Var} \theta_O \leq M^{-1} \|\mathcal{O}\|_\infty 4^s$, where $s$ is the number of qubits for which $\mathcal{O}$ acts non-trivially, and $\|\mathcal{O}\|_\infty = \text{max} \sigma_\mathcal{O} = \text{spec norm}$ of $\mathcal{O}$, where $\sigma_{\mathcal{O}}$ is the spectral norm of $\mathcal{O}$. Hence, the moments $k \leq 3$ of the POVM for local shadow tomography [Eq. (S36)] are the same as the corresponding moments of the tomographic ensemble considered in our blocked protocol.

**Theorem 2** For any target state $\rho_S$ and observable $\mathcal{O}$ that acts non-trivially on a subset of blocks $T \subseteq \{1, \ldots, n\}$ [i.e. $\mathcal{O} = \mathbb{I}_T \otimes \mathcal{O}_T$] with corresponding Hilbert space dimensions $d_j$, the variance of the estimator $\hat{\theta}_O$ constructed using a POVM for which the $k \leq 3$ moments of the tomographic ensemble are of the form (S41) can be bounded as

$$\text{Var} \hat{\theta}_O \leq \frac{1}{M} \|\mathcal{O}\|_\infty^2 L(\{d_j\}_T)$$

where $L(\{d_j\}_T) \leq \prod_{j \in T} \begin{cases} 2d_j & d_j \leq 4 \\ 3d_j^2 & d_j > 4 \end{cases}$

(S42)
A full definition of function $L(\{d_j\}_T)$ is given in Eq. (S49); here we give an upper bound that takes a particularly simple form. When we set $d_j = 2$ for all $j$, the precise value of $L(\{2\}^{x|T|})$ is $(3.7470\ldots)^|T|$, which gives a tighter bound than that proved for random Pauli measurements in Ref. [23].

**Proof of Theorem 2.**—We begin by substituting (S41) into our expression for the variance (6), and separating the factors corresponding to $T$ and its complement $\bar{T}$

$$\text{Var} \hat{\theta}_O = \frac{1}{M} \text{Tr} \left[ \left( \rho_S \otimes (\mathcal{M}^{-1}_T[\mathbb{I}_T] \otimes \mathcal{M}^{-1}_T[\mathcal{O}_T]) \right)^{\otimes 2} \otimes \mathcal{E}_{\text{Haar},j}^{(3)} \right]$$

(S43)

where $\mathcal{M}^{-1}_T = \bigotimes_{j \in T} \mathcal{M}^{-1}_j$ is the inverse map acting on blocks within $T$, and similarly for $\mathcal{M}^{-1}_{\bar{T}}$. Using the universal blocked form of the inverse map $\mathcal{M}^{-1}_j[C_j] = (d_j + 1)C_j - \text{Tr}[C_j] \mathbb{I}_j$ [which follows from (S41)], we note that $\mathcal{M}^{-1}_j[\mathbb{I}_j] = \mathbb{I}_j$. We can therefore perform a partial trace over the blocks in $\bar{T}$, giving

$$\text{Var} \hat{\theta}_O = \frac{1}{M} \text{Tr} \left[ \left( \rho_T \otimes \mathcal{M}^{-1}_T[\mathcal{O}_T] \otimes \mathcal{M}^{-1}_T[\mathcal{O}_T] \right) \cdot \bigotimes_{j \in T} \mathcal{E}_{\text{Haar},j}^{(3)} \right]$$

(S44)

where $\rho_T = \text{Tr}_T \rho_S$ is the reduced density matrix on $T$. Now we use the fact that $\mathcal{M}^{-1}$ is self-adjoint with respect to the Hilbert-Schmidt inner product, allowing us to move the inverse map onto the Haar moments

$$\text{Var} \hat{\theta}_O = \frac{1}{M} \text{Tr} \left[ (\rho_T \otimes \mathcal{O}_T \otimes \mathcal{O}_T) \cdot \bigotimes_{j \in T} \left[ (\text{id}_j \otimes \mathcal{M}^{-1}_j \otimes \mathcal{M}^{-1}_j) \otimes \mathcal{E}_{\text{Haar},j}^{(3)} \right] \right]$$

(S45)

We now aim to characterize the object inside the direct product in the above. Using the representation of the $k = 3$ moments of the Haar ensemble (S38), we can study the effect of the map $\mathcal{Q}_j := (\text{id}_j \otimes \mathcal{M}^{-1}_j \otimes \mathcal{M}^{-1}_j)$ on each permutation operator $\pi_{\sigma}$ separately. Using cycle notation to denote the 6 elements of $\Sigma_3$ as $\{e, (1 2), (2 3), (1 3), (1 2 3), (1 3 2)\}$, a straightforward calculation shows

- $\mathcal{Q}_j[\pi_{e}] = \pi_{e}$
- $\mathcal{Q}_j[\pi_{(1 2)}] = (d_j + 1)^2 \pi_{(1 2)} - (2d_j + 1) \pi_{e}$
- $\mathcal{Q}_j[\pi_{(1 3)}] = (d_j + 1) \pi_{(1 3)} - \pi_{e}$
- $\mathcal{Q}_j[\pi_{(2 3)}] = (d_j + 1) \pi_{(2 3)} - \pi_{e}$
- $\mathcal{Q}_j[\pi_{(1 2 3)}] = (d_j + 1)^2 \pi_{(1 2 3)} - (d_j + 1)[\pi_{(1 3)} + \pi_{(2 3)}] + \pi_{e}$
- $\mathcal{Q}_j[\pi_{(1 3 2)}] = (d_j + 1)^2 \pi_{(1 3 2)} - (d_j + 1)[\pi_{(1 3)} + \pi_{(2 3)}] + \pi_{e}$

(S46a) - (S46f)

After taking the required sum over permutations in $\mathcal{E}_{j}^{(3)}$, the direct product in (S45) becomes $\bigotimes_{j \in T} R_j$, where we define $R_j$ as

$$R_j = (d_j + 1)^2[\pi_{(1 2)} + \pi_{(1 2 3)} + \pi_{(1 3 2)}] - (d_j + 1)[\pi_{e} + \pi_{(1 3)} + \pi_{(2 3)}]$$

(S47)

We now employ Hölder’s inequality $\|X \cdot Y\|_1 \leq \|X\|_p \|Y\|_q$, where $\|X\|_p := \text{Tr}[|X|^p]^{1/p}$ is the $p$th Schatten norm of an arbitrary matrix $X$ with $|X| := \sqrt{X^\dagger X}$, and $p, q \in [1, \infty]$ are chosen arbitrarily subject to the condition $1/p + 1/q = 1$. This gives an upper bound

$$\text{Var} \hat{\theta}_O \leq \frac{1}{M} \|\rho_T\|_p \|\mathcal{O}_T\|_q \prod_{j \in T} \frac{\|R_j\|_q}{d_j(d_j + 1)(d_j + 2)}$$

$$= \frac{1}{M} \|\mathcal{O}_T\|_q \prod_{j \in T} \frac{d_j^{2/p - 1} \|R_j\|_q}{d_j + 1}(d_j + 2)$$

(S48)

where in the last step we use the inequality $\|X\|_p \leq n^{1/p}\|X\|_\infty$ for an $n \times n$ matrix $X$, as well as $\|\rho\|_p \leq 1$ for any valid density matrix and $p \leq 1$. To make use of this bound, we need to compute the Schatten norm, which is equal to the $p$-norm of the vector of singular values of $R_j$. By considering the action of $R_j$ on states of the form...
\[
\sum_{\sigma \in \Sigma_3} a_\sigma |x_{\sigma(1)} x_{\sigma(2)} x_{\sigma(3)}\rangle, \quad \text{where } x_{1,2,3} \in \{1, \ldots, d_j\} \text{ label an orthonormal basis for the Hilbert space of block } j, \text{ one can show that there are four distinct singular values of } R_j, \text{ equal to } 0, 3d_j(d_j+1), (d_j+1)(d_j+2), \text{ and } 2(d_j+1)(d_j+2), \text{ with respective degeneracies } 2\binom{d_j+1}{3}, \binom{d_j+2}{3}, \binom{d_j}{3}, \text{ and } 2\binom{d_j+1}{3}.
\]

At this point we define the function \( L(\{d_j\}_T) \) as the optimal value of the product in (S48). Specifically,
\[
L(\{d_j\}_T) = \min_{p \in [1, \infty]} \prod_{j \in T} \frac{d_j^{2/p-1}}{(d_j+1)(d_j+2)} \left[ \binom{d_j+2}{3} \right] (3d_j(d_j+1))^{p/(p-1)} \left( \frac{d_j}{3} \right) (d_j+1)(d_j+2)^{p/(p-1)} \left[ \frac{2}{3} \right] (2d_j+1)^{p/(p-1)} \right)^{(p-1)/p}
\]

This expression is somewhat cumbersome, and so we calculate an upper bound of \( L(\{d_j\}_T) \) by setting \( p = 1, q = \infty \) in which case we can replace \( \|R_j\|_\infty \) with the maximum singular value, which is is \( 2(d_j+1)(d_j+2) \) for \( d_j \leq 4 \) and \( 3d_j(d_j+1) \) for \( d_j \geq 4 \). This is the result quoted in Theorem 2.

We observe numerically that when \( d_j \geq 4 \) for all \( j \), the minimum (S49) is obtained at \( p = 1 \), and so the inequality on the right hand side of (S42) becomes an equality. In the case of qubits \( d_j = 2 \), substituting the upper bound for \( L(\{d_j\}_T) \) given in (S42) reproduces the result \( \text{Var} \hat{\theta}_O \leq M^{-1} \|O\|_\infty^4 \text{Tr}[\rho_S^4] \) found in Ref. [23]. In fact, by optimizing over \( p \) we can find a tighter upper bound. Numerically we find that the optimal choice of \( p \) is 1.1764\ldots, which results in \( \|R_j\|_p = 3.7470\ldots \).

### Nonlinear functionals of \( \rho_S \)

For the majority of this paper, we have focussed on extraction of expectation values \( \langle O \rangle = \text{Tr}[O \rho_S] \), which are linear functionals of the system density matrix. Here, we describe how one can estimate nonlinear functionals of the form \( \text{Tr}[O(\rho^{\otimes \ell})] \), where \( O(\rho) \) is an arbitrary operator acting on a \( \ell \)-fold replicated Hilbert space. Examples of such quantities are (exponentials of) Rényi entropies \( \exp[-(\ell - 1)S^{(\ell)}] := \text{Tr}[\rho_S^{\ell}] \equiv \text{Tr}[\rho_A^{\otimes \ell}] \), as well as partially transposed moments \( \text{Tr}[\rho_A^{\otimes \ell}] \) (where \( T_A \) denotes a partial transpose), which are used to construct entanglement negativities [53–55].

The construction of nonlinear estimators here follows the same logic as those in Ref. [23]: First, for each repetition \( r = 1, \ldots, M \) one constructs an unbiased estimator \( \hat{\rho}_S^{(r)} \) of the full system density matrix, i.e. \( \mathbb{E}[\hat{\rho}_S^{(r)}] = \rho_S \). In our case, the estimator can be constructed from a set of measurement outcomes using the optimal inverse map (4)
\[
|\hat{\rho}_S^{(r)}\rangle = G_0|m^{(r)}\rangle
\]

Using \( G_0 F = \text{id} \) and \( \mathbb{E}[m^{(r)}] = F[\rho_S] \), we can show that the above is indeed an unbiased estimator of the system density matrix.

Then, using these \( M \) independent estimators, \( U \)-statistics can be used [56] to construct an unbiased estimator of \( \text{Tr}[O(\rho^{\otimes \ell})] \). To be specific, one considers all choices of \( r_1 \neq r_2 \neq \cdots \neq r_\ell \), such that the estimators \( \rho^{(r_1)}, \ldots, \rho^{(r_\ell)} \) are statistically independent. Each subset of runs can be used to construct an estimator, and taking an average over all these gives
\[
\hat{\theta}_{O(\rho)} = \frac{1}{M(M-1)(M-\ell+1)} \sum_{r_1 \neq \cdots \neq r_\ell} \text{Tr} \left[ O(\hat{\rho}_S^{(r_1)} \otimes \cdots \otimes \hat{\rho}_S^{(r_\ell)}) \right]
\]

The above is an unbiased estimator by virtue of the statistical independence of all \( \hat{\rho}_S^{(r_i)} \) inside the trace.

Determining the variance of (S51) requires a somewhat more involved calculation than for linear estimators. Calculations of this kind have been performed in the context of conventional shadow tomography with randomized measurements [55, 57]. Here we simplify matters by focusing on the \( M \to \infty \) limit. Using the arguments of Ref. [56], which apply generally to \( U \)-statistics of any kind, one can show that the variance takes an asymptotic form
\[
\text{Var} \hat{\theta}_{O(\rho)} = \frac{\ell^2}{M} \text{Var} \text{Tr} \left[ O^{\text{sym}}(\hat{\rho}_S \otimes \hat{\rho}_S^{(\ell-1)}) \right] + O \left( \frac{1}{M^2} \right)
\]
where $O_{\ell}^{\text{sym}} = (\ell!)^{-1} \sum_{\sigma \in \Sigma_{\ell}} \pi_{\sigma} O_{\ell} \pi_{\sigma}^\dagger$ contains only the parts of $O_{\ell}$ that act in a symmetric fashion on all replicas, and $\hat{\rho}_S$ is the estimator (S50) for any choice of $r$. Using the explicit form of $G_0$ in (4), we have

$$\text{Var} \hat{\theta}_{O_{\ell}} = \frac{\ell^2}{M} \sum_m p_m \text{Tr} \left[ O_{\ell}^{\text{sym}} \left( G_0[m] \otimes \hat{\rho}_S^{\otimes (\ell-1)} \right) \right]^2 + O \left( \frac{1}{M^2} \right)$$

$$= \frac{\ell^2}{M} \text{Tr} \left[ \left( \rho_S \otimes M \right)^{-1} \left[ O_1 \otimes G_0^{\otimes 2} \right] \mathcal{E}^{(3)} \right] + O \left( \frac{1}{M^2} \right)$$

(S53)

where $O_1 := \text{Tr}_{2,\ldots,\ell} [O_{\ell}^{\text{sym}} \cdot (I_1 \otimes \hat{\rho}_S^{\otimes (\ell-1)})]$ contains the partial trace over $(\ell-1)$ replicas, and $\mathcal{E}^{(3)}$ is the third moment of the tomographic ensemble (2). Again, this variance depends only on the $k \leq 3$ moments of the tomographic ensemble, and so when the ensemble forms a 3-design (which generically occurs in our protocol without conservation laws), the variance will be the same as the corresponding estimators in conventional shadow tomography.
