

PSEUDO-RANDOM NUMBER GENERATION WITH β -ENCODERS

CHARLENE KALLE, EVGENY VERBITSKIY, AND BENTHEN ZEEGERS[†]

ABSTRACT. The β -encoder is an analog circuit that converts an input signal $x \in [0, 1]$ into a finite bit stream $\{b_i\}$. The bits $\{b_i\}$ are correlated and therefore are not immediately suitable for random number generation, but they can be used to generate bits $\{a_i\}$ that are (nearly) uniformly distributed. In this article we study two such methods. In the first part the bits $\{a_i\}$ are defined as the digits of the base-2 representation of the original input x . Under the assumption that there is no noise in the amplifier we then study a question posed by Jitsumatsu and Matsumura on how many bits b_1, \dots, b_m are needed to correctly determine the first n bits a_1, \dots, a_n . In the second part we show this method fails for random amplification factors. Nevertheless, even in this case, nearly uniformly distributed bits can still be generated from b_1, \dots, b_m using modern cryptographic techniques.

1. INTRODUCTION

Any real number $x \in [0, 1]$ can be represented in base 2 as

$$(1) \quad x = \sum_{n=1}^{\infty} \frac{a_n}{2^n}, \quad a_n \in \{0, 1\}.$$

With the exception of a countable set of dyadic rationals of the form $x = \frac{K}{2^N}$, $K, N \in \mathbb{Z}_+$, the representation (1) is unique. The digits $\{a_n = a_n(x)\}$ can be obtained iteratively as follows: let $x_0 = x$, and for $n \geq 1$, we let

$$(2) \quad a_n = \begin{cases} 0, & \text{if } 2x_{n-1} < 1, \\ 1, & \text{if } 2x_{n-1} \geq 1, \end{cases} \quad \text{and} \quad x_n = 2x_{n-1} - a_n.$$

Similarly, for $\beta \in (1, 2)$, any number $x \in [0, 1]$ can also be represented in *non-integer base* β as

$$(3) \quad x = \sum_{n=1}^{\infty} \frac{b_n}{\beta^n},$$

again with binary digits b_n in $\{0, 1\}$. (In fact, any number $x \in [0, \frac{1}{\beta-1}]$ has an expansion of the form (3).) Since $\beta \in (1, 2)$ is not an integer, Lebesgue almost all points x have uncountably many different β -expansions [EJK90, Sid03]. This somewhat curious fact from number theory has some interesting applications in signal processing. As is well known, for each $u \in [1, \frac{1}{\beta-1}]$ expansions of the form in (3) can be obtained in a similar fashion as the base 2 expansions by setting $x_0 = x$, and for $n \geq 1$,

$$(4) \quad b_n = \begin{cases} 0, & \text{if } \beta x_{n-1} < u, \\ 1, & \text{if } \beta x_{n-1} \geq u, \end{cases} \quad \text{and} \quad x_n = \beta x_{n-1} - b_n.$$

This iteration scheme is used in β -encoders, which were introduced in [DDGV02] by Daubechies et al. in 2002. Using an *amplifier* with amplification factor β and a *quantiser*

$$Q_u(y) = \begin{cases} 0, & \text{if } y < u, \\ 1, & \text{if } y \geq u, \end{cases}$$

Key words and phrases. β -encoder, binary expansions, Lochs' Theorem, random number generation.

for an input signal $x = x_0$ in $[0, 1]$ a β -encoder outputs bits $b_n = Q_u(\beta x_{n-1})$ where $x_n = \beta x - Q_u(\beta x_{n-1})$, see Figure 1, which corresponds to the iteration scheme in (4). In practice, however, due to the intrinsic presence of noise in analogue circuits, the amplification factor β and the threshold value u fluctuate during the operation of a β -encoder circuit. If we denote by $(\beta_n)_{n \geq 1}$ and $(u_n)_{n \geq 1}$ the consecutive (random) amplification factors β_n and threshold values u_n , respectively, used at each time step of the approximation algorithm, the β -encoder in reality outputs bits $b_n = Q_{u_n}(\beta_n x_{n-1})$ where $x_n = \beta_n x - Q_{u_n}(\beta_n x_{n-1})$. The robustness of the β -encoder in the A/D-conversion process has been studied in e.g. [DDGV06, DY06, War08, JW09, DGWY10, KHTA12, KHA12, SKM⁺13, MIS⁺15].

FIGURE 1. Iteration process of the β -encoder.

In recent years β -encoders were also considered as sources for random number generation, see [JMKA13, SJO15, JM16, KJ16]. If x is chosen uniformly at random in $[0, 1]$, then the digits $\{a_n(x)\}_{n \geq 1}$ from (1) form a sequence of binary independent identically distributed random variables with $\mathbb{P}(a_n = 0) = \mathbb{P}(a_n = 1) = \frac{1}{2}$. On the other hand, it is known that successive bits $\{b_n\}$ in the output of a β -encoder are correlated and therefore not immediately applicable as pseudo-random numbers. Under the assumption that the amplification factor β does not fluctuate, Jitsumatsu and Matsumura proposed in [JM16] a coding scheme which ‘removes’ the dependence between the bits and converts the output bits $\{b_n\}$ of the β -encoder into the binary digits $\{a_n\}$ in base 2 of the number it represents. It is verified in [JM16] that the resulting output sequences $\{a_n\}$ pass the NIST statistical test suite from [RSN⁺01], which shows that this method performs well as a pseudo-random number generator. A natural question asked in [JM16] is the following: If we use $\mathbf{u} = (u_n)_{n \geq 1}$ to denote the consecutive (random) threshold values u_n , what is the number $k(m, \mathbf{u}, x)$ of bits $\{b_n\}$ from the β -encoder that are necessary to obtain m digits in base 2 of the number x via this process? In [JM16] the lower bound $k(m, \mathbf{u}, x) \geq \frac{m \log 2}{\log \beta}$ was found.¹ The authors of [JM16] remarked that a theoretical analysis of the expected value of $k(m, \mathbf{u}, x)$ is relevant as an indication of the efficiency of the proposed pseudo-random number generator.

The question from [JM16] is reminiscent of the considerations of Lochs in [Loc64] from 1964, where Lochs asked how many regular continued fraction digits of a real number x one can determine from knowing only the first n decimal digits of x . If we call this number of digits $m_L(n, x)$, then Lochs’ Theorem states that for Lebesgue almost every $x \in [0, 1]$,

$$(5) \quad \lim_{n \rightarrow \infty} \frac{m_L(n, x)}{n} = \frac{6 \log 2 \log 10}{\pi^2}.$$

The somewhat mysterious expression on the right-hand side turns out to be a ratio of *entropies* of the interval maps $T(x) = 10x \bmod 1$ and $S(x) = 1/x \bmod 1$ that generate the decimal expansions and regular continued fraction expansions, respectively. Lochs’ result was extended in [DF01] to other types of number expansions including binary expansions and β -expansions by placing it in a dynamical systems framework, see also [BDK99]. These results are further generalized in [KVZ22] to number expansions generated by random dynamical systems. Unfortunately the results from

¹This bound was found in [JM16] for bits $\{b_n\}$ from a *scale-adjusted* β -encoder, that is, if the iteration scheme is given by (4) but with $u \in [\beta - 1, 1]$ and $x_n = \beta x_{n-1} - (\beta - 1)b_n$. This difference is not principal in the first three sections where the amplification factor is assumed to be fixed. However, in reality the amplifier and scale-adjuster are subject to noise as well, and to minimize this influence we therefore consider a model without scale-adjuster.

[Loc64, BDK99, DF01, KVZ22] do not immediately apply to the question from [JM16] due to the uncertainty in the threshold value u . In this article we adapt the methods from [DF01, KVZ22] to the specific iteration scheme of the β -encoder.

The first goal of this article is to address the question posed in [JM16]. In our first main result we recover the lower bound from [JM16] and we obtain a statement on an upper bound for $k(m, \mathbf{u}, x)$. More precisely, we obtain the following results. Here λ denotes the one-dimensional Lebesgue measure.

Theorem 1.1. *Consider $\beta \in (1, 2)$ and a sequence of thresholds $\mathbf{u} = (u_n)_{n \geq 1} \in [1, (\beta - 1)^{-1}]^{\mathbb{N}}$. For all $x \in [0, 1]$ and all $m \in \mathbb{N}$ it holds that*

$$(6) \quad k(m, \mathbf{u}, x) \geq \frac{m \log 2}{\log \beta}.$$

Moreover, for each $\varepsilon \in (0, 1)$ there exists a constant $C(\varepsilon) > 0$ such that for all $m \in \mathbb{N}$

$$(7) \quad \lambda\left(\left\{x \in [0, 1] : k(m, \mathbf{u}, x) - \frac{m \log 2}{\log \beta} > C(\varepsilon)\right\}\right) < \varepsilon.$$

From these bounds we obtain the following corollary on the asymptotic behaviour of the sequences $(k(m, \mathbf{u}, x))_{m \geq 1}$.

Corollary 1.1. *For any real positive sequence $(n_m)_{m \in \mathbb{N}}$ with $\lim_{m \rightarrow \infty} n_m = \infty$, each $\mathbf{u} \in [1, (\beta - 1)^{-1}]^{\mathbb{N}}$ and $\varepsilon > 0$ it holds that*

$$\lim_{m \rightarrow \infty} \lambda\left(\left\{x \in [0, 1] : \frac{1}{n_m} \left|k(m, \mathbf{u}, x) - \frac{m \log 2}{\log \beta}\right| > \varepsilon\right\}\right) = 0,$$

i.e., the sequence $\left(\frac{1}{n_m} (k(m, \mathbf{u}, x) - \frac{m \log 2}{\log \beta})\right)_{m \geq 1}$ converges to 0 in λ -probability.

In particular, the above corollary has the following implications:

- Taking $n_m = \sqrt{m}$ for each m gives a Central Limit Theorem result where the limiting distribution has zero variance;
- Taking $n_m = m$ for each m we retrieve a limit statement in the spirit of (5), but with convergence in probability instead of almost surely.

By adjusting the setup from [DF01] to suit our purposes, we obtain the stronger result of almost sure convergence for the specific sequence $(n_m)_{m \geq 1}$ with $n_m = m$ for each m that is stated in the next theorem.

Theorem 1.2. *For each $\mathbf{u} \in [1, (\beta - 1)^{-1}]^{\mathbb{N}}$, it holds that*

$$\lim_{m \rightarrow \infty} \frac{k(m, \mathbf{u}, x)}{m} = \frac{\log 2}{\log \beta} \quad \text{for } \lambda\text{-a.e. } x \in [0, 1].$$

More specifically, for typical x and large N one needs approximately $N \frac{\log 2}{\log \beta}$ output bits of the β -encoder to obtain N correct binary digits.

Since the implementation of β -encoders it has been observed that (like for the threshold value u) there is uncertainty about the precise value of β during the encoding process. The actual value of β can only be determined to lie within an interval $[\beta_{\min}, \beta_{\max}]$. Possible solutions to this problem were studied in [DGWY10, DY06, War08]. We will argue that in this case one is not able to extract a large number of digits (a_1, \dots, a_n) in the base 2 expansion of the input value x using the output bits (b_1, \dots, b_m) from the β -encoder. Nevertheless, the output bits (b_1, \dots, b_m) are still sufficiently random, and using modern cryptographic techniques, one is still able to extract n nearly independent bits from $\gamma n \frac{\log 2}{\log \beta}$ output bits, where $\gamma > 1$ is a fixed factor, which depends on how close to ‘nearly independent’ the final output bits should be.

The article is organised as follows. In the next section we introduce the necessary notation and preliminaries on base 2 expansions and β -expansions. In Section 3 we prove Theorem 1.1,

Corollary 1.1 and Theorem 1.2. Here it is assumed that the amplification factor is fixed and only the threshold value fluctuates. Finally, in Section 4 we discuss modern cryptographic techniques to apply for the case that the amplification factor fluctuates as well.

2. PRELIMINARIES

For a set A and an integer $m \geq 1$ we use the notation $A^m = \{(a_1, \dots, a_m) : a_i \in A, 1 \leq i \leq m\}$ and $A^{\mathbb{N}} = \{(a_k)_{k \geq 1} : a_k \in A, k \geq 1\}$. If I is an interval in the real line, then we write ∂I for the set containing the two boundary points of I and we use I^- and I^+ to denote the left and right endpoints of I , respectively.

For each $m \geq 1$ the collection of *dyadic intervals of order m* is given by

$$\mathcal{D}_m = \left\{ \left[\frac{k}{2^m}, \frac{k+1}{2^m} \right) : 0 \leq k \leq 2^m - 1 \right\}.$$

If we write the point $\frac{k}{2^m} = \sum_{i=1}^m \frac{d_i}{2^i}$, $d_i \in \{0, 1\}$, in its binary expansion, then we see that the interval $\left[\frac{k}{2^m}, \frac{k+1}{2^m} \right)$ contains precisely those $x \in [0, 1)$ that have d_1, \dots, d_m as their first m binary digits. For each $x \in [0, 1)$ and each $m \geq 1$ there is a unique element of \mathcal{D}_m that contains x . We denote this interval by $\mathcal{D}_m(x)$. Then

$$(8) \quad \lambda(\mathcal{D}_m(x)) = 2^{-m}.$$

Hence, each collection \mathcal{D}_m is a partition of $[0, 1)$ by intervals of length 2^{-m} . By adding the point 1 to the last interval of \mathcal{D}_m we obtain a partition of the closed interval $[0, 1]$ without disturbing any of the properties mentioned above.

FIGURE 2. The graph of one of the maps T_u is shown for $\beta = \frac{1+\sqrt{5}}{2}$, the golden mean. The yellow area in the middle relates to the interval in which the threshold value u may be chosen. At the top we see the two intervals $\mathcal{I}_{(0)}$ and $\mathcal{I}_{(1)}$ that are the elements of the cover \mathcal{I}_1 .

Usually A/D-converters rely on binary expansions of numbers to produce good approximations of the input signal. The β -encoder is based on β -expansions instead. Fix a value of $\beta \in (1, 2)$. An expression of the form

$$x = \sum_{n \geq 1} \frac{b_n}{\beta^n}, \quad b_n \in \{0, 1\},$$

is called a β -expansion of x . The set of numbers that can be written in this way is equal to the interval $\left[0, \frac{1}{\beta-1}\right]$. We now briefly explain how one can get a β -expansion of a number x from the β -encoder introduced in the introduction with varying threshold values u_n .

For each $u \in [1, (\beta-1)^{-1}]$ define the interval map $T_u : [0, (\beta-1)^{-1}] \rightarrow [0, (\beta-1)^{-1}]$ by

$$(9) \quad T_u(y) = \begin{cases} \beta y, & \text{if } y < \frac{u}{\beta}, \\ \beta y - 1, & \text{if } y \geq \frac{u}{\beta}. \end{cases}$$

The graph of such a map is shown in Figure 2. If we let u_n denote the threshold value of the quantiser at time n , then the dynamics of the β -encoder can be represented as

$$(10) \quad x_n = T_{u_n}(x_{n-1}) = T_{u_n} \circ \cdots \circ T_{u_1}(x), \quad n \geq 1.$$

For each $n \geq 1$, set $b_n = b_n(x) = 0$ if $\beta x_{n-1} < u_n$ and 1 otherwise. Putting $x_0 = x$, then for each $n \geq 1$,

$$T_{u_n}(x_{n-1}) = \beta x_{n-1} - b_n,$$

so that

$$x = \sum_{i=1}^n \frac{b_i}{\beta^i} + \frac{T_{u_n} \circ \cdots \circ T_{u_1}(x)}{\beta^n}.$$

Since $T_{u_n} \circ \cdots \circ T_{u_1}(x) \in [0, (\beta-1)^{-1}]$ holds for each n , we immediately conclude that $x = \sum_{n=1}^{\infty} \frac{b_n}{\beta^n}$. From Figure 2 it becomes clear that each threshold value u_n must lie in the interval $[1, (\beta-1)^{-1}]$ to obtain a recursive process and bits that correspond to β -expansions. It follows from [DdV05, Theorem 2], where for the case that $\beta \in (1, 2)$ only the choices $u_n \in \{1, (\beta-1)^{-1}\}$ for each $n \geq 1$ are considered, that in fact all β -expansions can be generated using the above iteration process.

Remark 2.1. Note that if one starts this process with a number $x \in [0, 1]$, then typically $x_n > 1$ for many n . The reason to look at $x \in [0, 1]$ instead of $x \in [0, \frac{1}{\beta-1}]$ is to make the comparison with the dyadic intervals $\mathcal{D}_m(x)$, which are defined on $[0, 1]$, easier.

Given the first k output bits b_1, \dots, b_k of the β -encoder, we know that the input signal $x \in [0, 1]$ has to satisfy

$$x \in \left[\sum_{n=1}^k \frac{b_n}{\beta^n}, \sum_{n=1}^k \frac{b_n}{\beta^n} + \sum_{n \geq k+1} \frac{1}{\beta^k} \right] = \left[\sum_{n=1}^k \frac{b_n}{\beta^n}, \sum_{n=1}^k \frac{b_n}{\beta^n} + \frac{1}{\beta^k(\beta-1)} \right].$$

For each $b_1, \dots, b_k \in \{0, 1\}$ define

$$\mathcal{I}_{(b_1, \dots, b_k)} = \left[\sum_{n=1}^k \frac{b_n}{\beta^n}, \sum_{n=1}^k \frac{b_n}{\beta^n} + \frac{1}{\beta^k(\beta-1)} \right].$$

Comparable to the partitions \mathcal{D}_m for binary expansions, we consider for each $k \geq 1$ the *cover* \mathcal{I}_k of $[0, (\beta-1)^{-1}]$ associated to β -expansions given by

$$\mathcal{I}_k = \{\mathcal{I}_{(b_1, \dots, b_k)} : b_i \in \{0, 1\}, 1 \leq i \leq k\}.$$

See Figure 2 for an illustration of $\mathcal{I}_1 = \{\mathcal{I}_{(0)}, \mathcal{I}_{(1)}\}$.

If for $k \geq 1$ the first k output bits of the β -encoder for an input signal $x \in [0, 1]$ and a threshold value sequence $\mathbf{u} \in [1, (\beta-1)^{-1}]^{\mathbb{N}}$ are b_1, \dots, b_k , then we set

$$\mathcal{I}_k(\mathbf{u}, x) = \mathcal{I}_{(b_1, \dots, b_k)},$$

since the information that the bits b_1, \dots, b_k give us is that x is contained in this interval. Note that

$$(11) \quad \lambda(\mathcal{I}_k(\mathbf{u}, x)) = \frac{1}{\beta^k(\beta-1)}.$$

Furthermore,

$$(12) \quad k(m, \mathbf{u}, x) = \inf\{k \geq 1 : \mathcal{I}_k(\mathbf{u}, x) \subseteq \mathcal{D}_m(x)\}.$$

3. FIXED AMPLIFICATION FACTOR

In this section we prove our first main results where the amplification factor is assumed to be fixed. We start with the proof of Theorem 1.1, which provides bounds for the quantities $k(m, \mathbf{u}, x)$. This proof is inspired by the proof of [Her09, Theorem 2.3].

Proof of Theorem 1.1. Fix $\mathbf{u} = (u_n)_{n \geq 1} \in [1, (\beta - 1)^{-1}]^{\mathbb{N}}$. For all $m \in \mathbb{N}$ and $x \in [0, 1]$ we find by (8) and (11) that $\lambda(\mathcal{D}_m(x)) = 2^{-m}$ and $\lambda(\mathcal{I}_{k(m, \mathbf{u}, x)}(\mathbf{u}, x)) = \beta^{-k(m, \mathbf{u}, x)}(\beta - 1)^{-1}$. Hence,

$$(13) \quad k(m, \mathbf{u}, x) - \frac{m \log 2}{\log \beta} + \frac{\log(\beta - 1)}{\log \beta} = \frac{1}{\log \beta} \cdot \log \left(\frac{\lambda(\mathcal{D}_m(x))}{\lambda(\mathcal{I}_{k(m, \mathbf{u}, x)}(\mathbf{u}, x))} \right).$$

Furthermore, by the definition of $k(m, \mathbf{u}, x)$ we have $\mathcal{I}_{k(m, \mathbf{u}, x)}(\mathbf{u}, x) \subseteq \mathcal{D}_m(x)$ and since $\beta \in (1, 2)$ the above yields

$$k(m, \mathbf{u}, x) \geq \frac{m \log 2}{\log \beta} - \frac{\log(\beta - 1)}{\log \beta} > \frac{m \log 2}{\log \beta}.$$

This gives (6).

For (7) let $\varepsilon \in (0, 1)$ and fix some integer $m \geq 1$. By the definition of $k(m, \mathbf{u}, x)$ we have that $\mathcal{I}_{k(m, \mathbf{u}, x)-1}(\mathbf{u}, x) \not\subseteq \mathcal{D}_m(x)$. Hence, the distance between x and the nearest boundary point of $\mathcal{D}_m(x)$, denoted by $|x - \partial \mathcal{D}_m(x)|$, is at most equal to $\lambda(\mathcal{I}_{k(m, \mathbf{u}, x)-1}(\mathbf{u}, x))$. Furthermore, we have

$$\log \lambda(\mathcal{I}_{k(m, \mathbf{u}, x)-1}(\mathbf{u}, x)) - \log \lambda(\mathcal{I}_{k(m, \mathbf{u}, x)}(\mathbf{u}, x)) = \log \beta.$$

Together this gives that

$$(14) \quad \log \left(\frac{\lambda(\mathcal{D}_m(x))}{\lambda(\mathcal{I}_{k(m, \mathbf{u}, x)}(x))} \right) \leq \log \lambda(\mathcal{D}_m(x)) + \log \beta - \log |x - \partial \mathcal{D}_m(x)|.$$

We slightly adjust the intervals in \mathcal{D}_m by removing small intervals at the endpoints: For each $m \in \mathbb{N}$ and interval $J \in \mathcal{D}_m$, let J' be the interval obtained by removing on both ends of J an interval of length $\frac{\varepsilon}{2} \cdot 2^{-m}$ and let $C_m = \bigcup_{J \in \mathcal{D}_m} J'$. Then $\lambda(J') = (1 - \varepsilon) \cdot 2^{-m}$ and $\lambda(C_m) = 1 - \varepsilon$. For $x \in C_m$ we have the bound $|x - \partial \mathcal{D}_m(x)| \geq \frac{\varepsilon}{2} \lambda(\mathcal{D}_m(x))$. Combining this with (13) and (14) gives for each integer $m \in \mathbb{N}$ and each $x \in C_m$ that

$$k(m, \mathbf{u}, x) - \frac{m \log 2}{\log \beta} \leq \frac{\log \frac{2}{\varepsilon}}{\log \beta} + 1.$$

Hence, we obtain (7) with constant $C(\varepsilon) = \frac{\log \frac{2}{\varepsilon}}{\log \beta} + 1$. \square

Theorem 1.1 gives bounds on the value of $k(m, \mathbf{u}, x)$ and immediately leads to the statement on the asymptotics of the sequence $(k(m, \mathbf{u}, x))_{m \geq 1}$ from Corollary 1.1 that we prove next.

Proof of Corollary 1.1. Let $(n_m)_{m \geq 1}$ be a sequence of positive real numbers that satisfy $\lim_{m \rightarrow \infty} n_m = \infty$. From (6) we get that for each $x \in [0, 1]$ and $m \in \mathbb{N}$,

$$\frac{1}{n_m} \left(k(m, \mathbf{u}, x) - \frac{m \log 2}{\log \beta} \right) \geq 0.$$

Hence, it suffices to show that for all $\delta, \varepsilon > 0$ there exists an $M \in \mathbb{N}$ such that for all $m \geq M$ we have

$$\lambda \left(\left\{ x \in [0, 1] : \frac{1}{n_m} \left(k(m, \mathbf{u}, x) - \frac{m \log 2}{\log \beta} \right) > \varepsilon \right\} \right) < \delta.$$

This immediately follows from (7) by taking $M \in \mathbb{N}$ big enough such that $\frac{C(\delta)}{n_m} \leq \varepsilon$ for all $m \geq M$, which is possible because $\lim_{m \rightarrow \infty} n_m = \infty$. \square

As we saw in the introduction, by choosing $n_m = m$ for all $m \geq 1$, Corollary 1.1 gives a limit statement reminiscent of Lochs' Theorem, but with convergence in probability. Our final result, Theorem 1.2, shows that this limit statement also holds almost surely. The proof we present for Theorem 1.2 below is inspired by the proof of [DF01, Theorem 4].

Proof of Theorem 1.2. Fix some $\mathbf{u} \in [\beta - 1, 1]^\mathbb{N}$. It follows from (6) that for all $x \in [0, 1]$

$$\liminf_{m \rightarrow \infty} \frac{k(m, \mathbf{u}, x)}{m} \geq \frac{\log 2}{\log \beta}.$$

Conversely, let $\varepsilon \in (0, 1)$ and for each $m \geq 1$ define $\bar{k}(m) = \lceil (1 + \varepsilon) \frac{m \log 2}{\log \beta} \rceil$. Let

$$\begin{aligned} \mathcal{P}_m &= \{x \in [0, 1] : \mathcal{I}_{\bar{k}(m)}(\mathbf{u}, x) \not\subseteq \mathcal{D}_m(x)\} \\ &\subseteq \bigcup_{B \in \mathcal{D}_m} \bigcup_{A \in \mathcal{I}_{\bar{k}(m)} : A \not\subseteq B} A \cap B \\ &\subseteq \bigcup_{B \in \mathcal{D}_m} [B^-, B^- + \beta^{-(1+\varepsilon)} \frac{m \log 2}{\log \beta}] \cup [B^+ - \beta^{-(1+\varepsilon)} \frac{m \log 2}{\log \beta}, B^+]. \end{aligned}$$

Since \mathcal{D}_m has $2^m = \beta^{\frac{m \log 2}{\log \beta}}$ elements, we have

$$\lambda(\mathcal{P}_m) \leq \beta^{\frac{m \log 2}{\log \beta}} \cdot 2 \cdot \beta^{-(1+\varepsilon) \frac{m \log 2}{\log \beta}} \leq 2 \cdot \beta^{-\varepsilon \frac{m \log 2}{\log \beta}} = 2 \cdot 2^{-\varepsilon m},$$

which gives that $\sum_{m=1}^{\infty} \lambda(\mathcal{P}_m) < \infty$. From the Borel-Cantelli Lemma it follows that

$$\lambda(\{x \in [0, 1] : x \in \mathcal{P}_m \text{ for infinitely many } m \in \mathbb{N}\}) = 0.$$

Hence,

$$\lambda(\{x \in [0, 1] : \exists M \in \mathbb{N} \text{ s.t. } \forall m \geq M \mathcal{I}_{\bar{k}(m)}(\mathbf{u}, x) \subseteq \mathcal{D}_m(x)\}) = 1,$$

or in other words, for Lebesgue almost all $x \in [0, 1]$ there exists an $M \in \mathbb{N}$ such that for all $m \geq M$ it holds that $k(m, \mathbf{u}, x) \leq \bar{k}(m)$. This gives

$$\limsup_{m \rightarrow \infty} \frac{k(m, \mathbf{u}, x)}{m} \leq \limsup_{m \rightarrow \infty} \frac{\bar{k}(m)}{m} = (1 + \varepsilon) \frac{\log 2}{\log \beta}, \quad \lambda\text{-a.e.}$$

Since $\varepsilon > 0$ was arbitrary, this concludes the proof. \square

Remark 3.1. Note that the first part of the previous proof holds for all $x \in [0, 1]$. It is the second part that only holds Lebesgue almost everywhere.

4. RANDOM AMPLIFICATION FACTOR

In practice it is not only the threshold value u that is subject to fluctuations present in the circuit, but also the amplification factor β . This issue and its implications for signal processing were discussed extensively in [DY06, War08, DGWY10]. Under some extra assumptions, e.g., amplification factors varying slowly and smoothly, one can find some ways to remedy this issue. However, in the general case, as the following simple consideration shows, in the presence of random amplification factors, one cannot expect to reliably determine a *significant number* of digits in the base 2 expansion of the input signal x by linking them to the digits from a random β -expansion of x .

Let us start by modeling the random amplification factors. Suppose that at each iteration the amplification factor β assumes a random value in some interval $[\beta_{\min}, \beta_{\max}] \subseteq (1, 2)$. Denote by $\boldsymbol{\beta} = (\beta_n)_{n \geq 1} \in [\beta_{\min}, \beta_{\max}]^\mathbb{N}$ the corresponding sequence. Similarly, we denote by $\mathbf{u} = (u_n)_{n \geq 1}$ again the sequence of the corresponding random threshold values. We assume $u_n \in [1, (\beta_{\max} - 1)^{-1}]$ for all n . As we will see below, the sequence \mathbf{u} will not have any effect on the conclusions.

Again, randomly choose $x_0 = x$ uniformly in $[0, 1]$. The bits b_n , $n \geq 1$, are defined iteratively by

$$(15) \quad b_n = Q_{u_n}(\beta_n x_{n-1}) = \begin{cases} 0, & \text{if } \beta_n x_{n-1} < u_n, \\ 1, & \text{if } \beta_n x_{n-1} \geq u_n \end{cases}, \text{ and } x_n = \beta_n x_{n-1} - b_n.$$

Thus for all n , one has

$$(16) \quad x = \sum_{i=1}^n \frac{b_i}{\prod_{j=1}^i \beta_j} + \frac{x_n}{\prod_{j=1}^n \beta_j}.$$

Lemma 4.1. *We have $x_n \leq (\beta_{\max} - 1)^{-1}$ for all n .*

Proof. We have $x_0 \leq 1 \leq (\beta_{\max} - 1)^{-1}$. Now suppose $x_n \leq (\beta_{\max} - 1)^{-1}$ holds for some n . If $b_{n+1} = 0$, then

$$x_{n+1} = \beta_{n+1}x_n - b_{n+1} = \beta_{n+1}x_n < u_{n+1} \leq (\beta_{\max} - 1)^{-1}.$$

On the other hand, if $b_{n+1} = 1$, then

$$x_{n+1} = \beta_{n+1}x_n - 1 \leq \frac{\beta_{n+1}}{\beta_{\max} - 1} - 1 \leq \frac{\beta_{\max} - \beta_{\max} + 1}{\beta_{\max} - 1} = (\beta_{\max} - 1)^{-1}.$$

So the statement holds in both cases. \square

Setting $\varkappa = (\beta_{\max} - 1)^{-1}$, it follows from the above lemma and (16) that

$$(17) \quad 0 \leq x - \sum_{i=1}^n \frac{b_i}{\prod_{j=1}^i \beta_j} \leq \frac{\varkappa}{\beta_{\min}^n} \rightarrow 0 \text{ as } n \rightarrow \infty.$$

Hence, the digits b_n correspond to an expansion of x of the form $x = \sum_{i=1}^{\infty} \frac{b_i}{\prod_{j=1}^i \beta_j}$. These are called a *Cantor real base expansions* and are studied in [CC21].

However, given the first m output digits b_1, \dots, b_m , without exact knowledge on the sequence β of random β -encoder amplifications, the only certain conclusion about the location of $x = x_0$ one can draw from (16) is that

$$x \in \hat{\mathcal{I}}_{(b_1, \dots, b_m)} := \left[\sum_{k=1}^m \frac{b_k}{\beta_{\max}^k}, \sum_{k=1}^m \frac{b_k}{\beta_{\min}^k} + \frac{\varkappa}{\beta_{\min}^m} \right].$$

The immediate conclusion is that the length $\hat{\mathcal{I}}_{(b_1, \dots, b_m)}$ does not converge² to 0 as $m \rightarrow \infty$, and hence we can not reliably determine a large number of binary digits of x . Hence, under the assumption that amplification factors fluctuate in the β -encoder circuit, one cannot guarantee the quality of the corresponding pseudo-random number generators studied earlier in the literature.

Nevertheless, it is absolutely clear, that the ‘random’ β -expansion circuit does produce digits (b_m) which are sufficiently random, and hence can, in principle, be used in random number generators. The natural practical questions are how much randomness is in (b_1, \dots, b_m) , and how can one *extract* this randomness?

Let us start with the first question. Suppose $\beta = (\beta_n)$ is a random process of random amplification factors assuming values $\beta_n \in [\beta_{\min}, \beta_{\max}]$ for all n . We denote by ρ the corresponding probability law on $[\beta_{\min}, \beta_{\max}]^{\mathbb{N}}$. As we will see, the threshold values $\mathbf{u} = (u_n)$ will not be important. For convenience we will assume $u_n = 1$ for all n . The initial point $x = x_0$ will be chosen uniformly in $[0, 1]$. Recall that λ denotes the Lebesgue measure on $[0, 1]$. Let $\Omega = [\beta_{\min}, \beta_{\max}]^{\mathbb{N}} \times [0, 1]$ and let $\mathbb{P} = \rho \times \lambda$ denote the corresponding probability law. Consider now the first m β -digits (b_1, \dots, b_m) obtained according to (15). We will view $b_1 = b_1(\omega), \dots, b_m = b_m(\omega)$ as random variables on Ω with $\omega = (\beta, x_0)$ distributed according to $\mathbb{P} = \rho \times \lambda$.

One way to quantify randomness in (b_1, \dots, b_m) is to estimate the so-called *min-entropy* $\mathbf{H}_{\infty}(\mathbb{P}_m)$ of the corresponding probability distribution \mathbb{P}_m on the space of binary strings of length m . If we write $c_1^m := c_1 \cdots c_m \in \{0, 1\}^m$ for a word of length m , then

$$\begin{aligned} \mathbf{H}_{\infty}(\mathbb{P}_m) &:= \min_{c_1^m \in \{0, 1\}^m} \log_2 \frac{1}{\mathbb{P}_m(c_1^m)} = -\log_2 \max_{c_1^m \in \{0, 1\}^m} \mathbb{P}_m(c_1^m) \\ &= -\log_2 \max_{c_1^m \in \{0, 1\}^m} \mathbb{P}(\{\omega \in \Omega : b_1(\omega) = c_1, \dots, b_m(\omega) = c_m\}). \end{aligned}$$

²Unless all β -digits b_n are 0

The lower bound on $\mathbf{H}_\infty(\mathbb{P}_m)$ is relatively straightforward: indeed, for any $c_1^m \in \{0, 1\}^m$, by the law of total probability,

$$\begin{aligned} \mathbb{P}_m(c_1^m) &= \mathbb{P}(\{(\boldsymbol{\beta}, x) \in \Omega : b_1(\boldsymbol{\beta}, x) = c_1, \dots, b_m(\boldsymbol{\beta}, x) = c_m\}) \\ &= \int_{[\beta_{\min}, \beta_{\max}]^{\mathbb{N}}} \lambda\left(\left\{x \in [0, 1] : b_1(\boldsymbol{\beta}, x) = c_1, \dots, b_m(\boldsymbol{\beta}, x) = c_m\right\}\right) \rho(d\boldsymbol{\beta}). \end{aligned}$$

For fixed β_1, \dots, β_m , one has

$$\left\{x \in [0, 1] : b_1(\boldsymbol{\beta}, x) = c_1, \dots, b_m(\boldsymbol{\beta}, x) = c_m\right\} \subseteq \left[\sum_{i=1}^m \frac{c_i}{\prod_{j=1}^i \beta_j}, \sum_{i=1}^m \frac{c_i}{\prod_{j=1}^i \beta_j} + \frac{\varkappa}{\prod_{j=1}^m \beta_j}\right],$$

and hence,

$$\mathbb{P}_m(c_1^m) \leq \int_{[\beta_{\min}, \beta_{\max}]^{\mathbb{N}}} \frac{\varkappa}{\prod_{j=1}^m \beta_j} \rho(d\boldsymbol{\beta}) \leq \frac{\varkappa}{(\beta_{\min})^m} \int_{[\beta_{\min}, \beta_{\max}]^{\mathbb{N}}} \rho(d\boldsymbol{\beta}) = \frac{\varkappa}{(\beta_{\min})^m}.$$

Therefore,

$$(18) \quad \mathbf{H}_\infty(\mathbb{P}_m) \geq m \log_2 \beta_{\min} - \log_2 \varkappa.$$

This argument shows that the min-entropy of our physical source of randomness – the β -encoder circuit – grows linearly in m , and that the growth-rate is at least $\frac{\log \beta_{\min}}{\log 2}$, i.e., the entropy of the ‘worst’ or the least random β -transformation, which is present in the mix. A source X is called a *random (m, k) -source* if X takes values in $\{0, 1\}^m$ and $\mathbf{H}_\infty(X) \geq k$. The computation above shows that the string of the first m bits of the β -encoder $\mathbf{b}_m = (b_1, \dots, b_m)$ is an (m, k) -source for any $k \leq m \frac{\log \beta_{\min}}{\log 2} - \log_2 \varkappa$.

For the next step we turn to the theory of randomness extracts developed by 1980’s by Chor, Goldreich, Cohen, Wigderson, Zuckerman and many others (c.f., [Tre01, Wig19]). The basic idea is, given a sufficiently random binary vector of length m , $X \in \{0, 1\}^m$, find a possibly smaller integer n , $n \leq m$, and an extractor function Ext mapping from $\{0, 1\}^m$ into $\{0, 1\}^n$, such that $Y = \text{Ext}(X)$ is (nearly) uniformly distributed in $\{0, 1\}^n$. To formalize the idea further, we say that a (deterministic) ϵ -extractor Ext is mapping from $\{0, 1\}^m$ into $\{0, 1\}^n$ such that the distribution \mathbb{P}_Y of $Y = \text{Ext}(X)$ is close to the uniform distribution \mathbb{U}_n on $\{0, 1\}^n$ in the sense that

$$d_{\text{TV}}(\mathbb{P}_Y, \mathbb{U}_n) = \frac{1}{2} \sum_{w \in \{0, 1\}^n} |\mathbb{P}_Y(w) - 2^{-n}| < \epsilon,$$

where d_{TV} is the total variation metric. Unfortunately, a simple argument (e.g., [Raz05]) shows that it is not possible to construct a universal extractor, capable of producing an output bit, which is ϵ -close to uniform, $\epsilon < 1/2$, for all random vectors with $X \in \{0, 1\}^m$ with large min-entropy $\mathbf{H}_\infty(X) \geq m - 1$. Indeed, suppose that such an extractor $\text{Ext} : \{0, 1\}^m \rightarrow \{0, 1\}$ exists. Let

$$S_0 = \{x \in \{0, 1\}^m : \text{Ext}(x) = 0\} \text{ and } S_1 = \{x \in \{0, 1\}^m : \text{Ext}(x) = 1\}.$$

Note also, that since $S_0 \cup S_1 = \{0, 1\}^m$, one of the sets S_0 and S_1 has cardinality at least 2^{m-1} . Suppose for simplicity that $|S_0| \geq 2^{m-1}$ and consider a random element X_0 , which is uniformly distributed on S_0 . Then $\mathbf{H}_\infty(X_0) \geq m - 1$. However, $Y = \text{Ext}(X_0) = 0$ identically, and hence Y is not ϵ -close to \mathbb{U}_1 . Fortunately, one can turn to the so-called seeded randomness extractors.

A *seeded (k, ϵ) -extractor* is a function

$$\text{Ext} : \{0, 1\}^m \times \{0, 1\}^d \rightarrow \{0, 1\}^n$$

such that for every (m, k) -source X , the distribution of $Y = \text{Ext}(X, Z)$, where $Z \sim \mathbb{U}_d$, is ϵ -close to \mathbb{U}_n . A seeded extractor, if it exists, is able to take an arbitrary sufficiently random input X (measured in terms of its min-entropy), and, hopefully, a relatively short uniformly distributed random seed, to produce a nearly uniformly distributed output. The principal question is under which conditions on m, d, k, n , and ϵ , a seeded extractor exist. There are numerous results of such nature. Let us recall the following:

Theorem 4.1 (Theorem 1.5, [GUV09]). *For every constant $\alpha > 0$, and all positive integers n, k and all $\varepsilon > 0$, there is an explicit construction of a (k, ε) -extractor $\text{Ext} : \{0, 1\}^m \times \{0, 1\}^d \rightarrow \{0, 1\}^n$ with $d = O(\log m + \log(1/\varepsilon))$ and $n \geq (1 - \alpha)k$.*

Taking into account that the distribution of digits produced by the β -encoder has min-entropy at least of the order of $m \frac{\log \beta_{\min}}{\log 2}$, the above theorem states that we can produce $n = (1 - \alpha)m \frac{\log \beta_{\min}}{\log 2}$ of nearly uniformly distributed binary digits (a_1, \dots, a_n) . Equivalently, we need $m = \frac{1}{1 - \alpha} n \frac{\log 2}{\log \beta_{\min}}$ output bits of the random β -encoder to obtain n binary well-distributed bits.

One can compare this result with the result of Theorem 1.1, which states that we would need at least $n \frac{\log 2}{\log \beta}$ output bits of the β -encoder, while the more robust universal randomness extractor would require $\frac{1}{(1 - \alpha)} n \frac{\log 2}{\log \beta}$, i.e., only a fixed fraction more. Thus, the price we have to pay is rather small since the bits are produced by a relatively cheap circuit working at high clock frequency. Therefore, switching from a specific extraction scheme based on entropy encoding suggested by Jitsumatsu et al. [KJ16] to a universal randomness extractor does not constitute a significant limitation.

However, the important point we have not yet taken into account is the need to use a relatively short, but “purely random”, seed of length $d = O(\log m + \log(1/\varepsilon))$. In practice one does not have access to such sources of “pure randomness”. Fortunately, weak sources of randomness, such as β -encoders, can be used as seeds as well. This brings us to the discussion of extractors with weak random seeds. In [Raz05] the following definition of two-sources-extractors is given.

Definition 4.1. (Two-Sources-Extractor [Raz05]) A function $\text{Ext} : \{0, 1\}^{m_1} \times \{0, 1\}^{m_2} \rightarrow \{0, 1\}^n$ is an $[(m_1, k_1), (m_2, k_2) \mapsto n \sim \varepsilon]$ -two-sources-extractor if for every (m_1, k_1) source X_1 and every independent (m_2, k_2) -source X_2 , the distribution of the random variable $\text{Ext}(X_1, X_2)$ is ε -close to \mathbb{U}_n (i.e., the uniform distribution over $\{0, 1\}^n$).

Similarly, one can define source extractors for any number of sources $\ell \geq 2$,

$$\text{Ext} : \{0, 1\}^{m_1} \times \{0, 1\}^{m_2} \times \dots \times \{0, 1\}^{m_\ell} \rightarrow \{0, 1\}^n$$

such that the extractor $\text{Ext}(X_1, \dots, X_\ell)$ is ε -close to \mathbb{U}_n for all independent $(m_1, k_1), \dots, (m_\ell, k_\ell)$ -sources (X_1, \dots, X_ℓ) .

The theory of multiple source extractors was actively developed in the past 25 years. It turns out that there is a significant difference between the cases $\ell = 2$ and $\ell \geq 3$. The case $\ell = 2$ is substantially more complicated. It is indeed possible to construct good, efficient two-source extractors, say for $m_1 = m_2 = m$ with the min-entropy of at least $\frac{1}{2}m$.

Theorem 4.2. [Sha08] *For every constant $\delta > 0$ there is a constant $C > 0$ such that for large enough m , setting $k = (1/2 + \delta)m$ and $\varepsilon \leq 2^{-\log^4 m}$ there is an explicit $[(m, k), (m, k) \mapsto n \sim \varepsilon]$ -two-source extractor $\text{Ext} : \{0, 1\}^m \times \{0, 1\}^m \rightarrow \{0, 1\}^n$ for $n = 2k - C \log(1/\varepsilon)$.*

In our case, given the bound on min-entropy (18), that would necessarily imply that we need an extra assumption that

$$\beta_{\min} > \sqrt{2}.$$

It is not immediately clear whether such a restriction would constitute a serious limitation for applications, but it is clear that such an a priori assumption would be undesirable. On the other hand, if one turns to randomness extractors for ℓ weak sources with $\ell \geq 3$, assumptions on β_{\min} can be relaxed. Barak, Impagliazzo and Wigderson [BIW04] showed using techniques from additive combinatorics that for any $\delta > 0$, there exist randomness extractors requiring only $\ell = \text{poly}(1/\delta)$ independent $(m, \delta m)$ sources, where poly is some polynomial function. It means that assuming that $\beta_{\min} > 1$, i.e., $\beta_{\min} = 1 + \tilde{\delta}$ for some $\tilde{\delta} > 0$ is sufficient. These results were further improved by Raz [Raz05] who showed that $\ell = 3$ is indeed sufficient.

The final point of discussion is whether one could get $\ell > 1$ independent weak sources of randomness. This could be achieved by running the β -encoder several times, or, running it once, generating a very long series of bits $N \gg 1$, and then extracting strings of length m , with sufficiently large gaps between them.

ACKNOWLEDGMENTS

We would like to thank Yutaka Jitsumatsu for valuable discussions.
